selected from a series of sixteen cases of hypertrophied synovial villi, recently removed at operation, because they seemed to represent distinct tumor formations, and not simply the arborescent overgrowths of the synovial membrane, which are so commonly seen. Doubtless this condition of apparent tumor formation is nothing more than the end result of the villous hypertrophy, but clinically this condition is much the more important to recognize, for the removal of the growth not only rids the affected joint of the cause of its symptoms, but removes from it a source of internal trauma, which would permanently impair the function of the joint if allowed to remain. It is of great importance, then, to recognize these growths in the joints, and in view of the failure to find tuberculosis as the cause for the hypertrophy in any of the following cases, it seems reasonably certain that isolated villous hypertrophies, without more symptoms of joint disease, will not be found to be due to tuberculous infection, and consequently the radical operations, which the literature shows have been resorted to in certain cases, are not indicated because one finds villous hypertrophy on opening the joint. The clinical symptoms given are those of a foreign body in the joint, and not of disease of the bones or soft parts.

CASE I. M. C., a woman aged twenty-one years. Had always been well until July, 1901, when she first had pain referred to the left knee, accompanied by swelling, but no redness; unable to work. Entered the Boston City Hospital in July, and was treated with a splint for two weeks without effect. In August again entered hospital, and remained six weeks without relief. In January visited the Carney Out-Patient Clinic, at which time the left knee was held flexed about 10°; complete extension was not permitted; attempts at this caused much pain. Over the outer side of the joint at the level of the outer border of the patella was a very tender spot, the size of a ten-cent piece. Motion allowed in flexion without spasm. A quarter to one-half inch atrophy of the thigh and calf; no enlargement of the knee joint itself; no thickening of the capsule. A positive diagnosis could not be made; x-ray taken.

Operation, March 17, 1902. An incision 10 cm. long was made on the outer side of the joint, exposing the capsule, which was not thickened. On opening the joint a fatty mass was found attached to the fossa above the external condyle, from which it extended well up into the suprapatellar pouch, attached all about its margin, and fed by vessels from its under surface. The blood supply was quite good. When this growth was removed it was as large as the palm of an adult hand. March 24th stitches were removed, joint manipulated; no adhesions.

The specimen removed consisted of an irregular mass of fatty tissue, more or less lobulated. This was inclosed in a capsule and interspersed by a meshwork of fibrous tissue, giving to the mass a firmer consistency than is common to ordinary lipomata.

Microscopically the tissue was found to consist of bands of fibrous tissue, usually narrow, irregular and loosely woven together. Throughout this fibrous tissue were numerous blood vessels with thickened walls. Separating these fibrous areas were masses of adipose tissue of varying size, scattered throughout which were many small blood vessels, their lumina almost or quite obliterated, forming small islands in the surrounding fatty tissue. Scattered throughout the specimen were large areas of fibrous tissue, taking up the eosin stain but little and with but few staining nuclei; the fibers in many cases being broken up into small fragments, and in places forming an almost homogeneous mass.

CASE II. L. F., male, aged thirty-five years. Five years ago noticed swelling of the right knee, which was slightly painful and reddened. The knee felt feverish for two or three months. Later began to walk lame;

visited the Hot Springs without relief. Redness subsided and swelling remained. Two years later left knee began to swell, and one year ago the left ankle. Left knee was operated upon at the Massachusetts General Hospital in February, 1900, with relief for two or three weeks, after which symptoms recurred.

Examination.—Left knee slightly swollen, half an inch larger than right; 45° of motion in flexion, and within 5° of complete extension possible. Marked thickening of the capsule of the joint, particularly on either side of the patellar tendon. No spasm on motion; no surface temperature or redness; apparently condition of proliferated synovial fringes.

Operation.—Incision 5 cm. long, on inner side of the joint, exposing the capsule, which was very much thickened and quite vascular. On opening the joint the synovial surface was found to be congested, and the villi were much proliferated. Some cloudy fluid escaped. In it were fibrinous clots. The greatest proliferation of the villi was in the region of the ligamentum alae. An opening was made over the outer side of the joint; several large villi immediately presented in the wound; on the upper and outer side of the capsule of the joint was a fatty growth suspended from the synovial membrane, apparently a degenerated villus. This was the size of an English walnut. The fringes were removed and the lipoma dissected out. Convalescence has been uneventful since the operation was performed. Six months after the operation the function of the joint was practically normal, and the patient had been at his work as a street car conductor for some time.

The specimen consisted of several fringes removed from the synovial membrane close to the patella and on either side of the joint. They varied in length from 1 to 2.5 cm., and in thickness from .5 to 1 cm. Dark purple in color and very vascular. There was also a sessile mass, fatty in character, which was removed from the synovial membrane of the upper and outer portion of the joint. This was some 3 cm. in diameter, and appeared to be a fringe which had undergone fatty degeneration.

Microscopically the specimen was found to consist of adipose tissue interspersed by broad and more or less regularly arranged bands of connective tissue. In both varieties of tissue were numerous vessels, the larger being found for the most part in the latter, the smaller in the former tissue. The larger vessels showed marked thickening of their walls, the smaller were often wholly obliterated.

CASE III. A. S., a woman aged twenty-three years. For the past six months has complained of the left knee "catching" when in certain positions; not enough to throw her and not causing any acute signs of joint trauma, but enough to be of considerable annoyance, and making her feel uncertain in the use of the leg. These symptoms were gradual in their onset, and not connected with any known cause.

Examination.—A well-developed girl; over the outer side of the left knee joint can be felt a distinct fringe which seems fibrous and which the fingers slip over in palpating the joint. Joint motions perfectly free; one-half inch enlargement of the left knee; no atrophy of thigh or calf; no signs of acute disease.

Operation, Feb. 28, 1902. An incision was made over the outer aspect of the joint; no thickening of the capsule; no increase in vascularity. On incising the capsule a large fatty growth presented in the upper part of the joint, apparently growing from the synovial membrane and projecting well down under the upper half of the patella when the joint is flexed; also extending well over to the inner side of the joint. The vessels supplying the nourishment seemed to come from the parietal layer of the synovial membrane. This mass was dissected out and the wound closed with silk worm gut.

March 24, 1902, normal motions in the joint; no symptoms of the old trouble. The functional use is entirely restored.

The specimen consisted of a lobulated irregular mass of fatty tissue, the lobules held together by a meshwork of fibrous bands, giving the tissues a firmer consistency than is usual in lipomata. Markedly vascular.

Microscopically the specimen was found to consist of areas of adipose tissue traversed by bands of connective tissue, for the most part regular in arrangement and stain-

ing deeply, but there were some areas where the arrangement was loose and the staining feeble. The cortical portion contained well-defined areas densely infiltrated with small, round cells, which were entirely absent in the central portion.

CASE IV. Aug. 28, 1902. F. B. For about a year has had trouble with pain and swelling in the right knee. Came on gradually—all the symptoms coming at about the same time but without known cause. Condition has been much worse since a fall on Thanksgiving Day, 1901. Pain at any time independent of use, but is made worse by damp weather. Keeps her from sleeping sometimes. General health good. No trouble in the other joints except that the cervical spine has been annoying her some of late. The joint "catches" at times in a flexed position so that it cannot be straightened.

Examination.—Right knee one inch larger than the left. Joint capsule thickened and relaxed particularly below and on either side of the patella. Sensation of slipping in the joint over the inside of the patella above the line of the joint. Suggests either a fringe or the cartilage, probably the former. In bed at times the joint locks and the cords become tense.

Plaster for two weeks.

Sept. 11, 1902, soreness still persists. Swelling has gone down very much. Circumference over patella 43 cm.— $\frac{1}{2}$ cm. less in circumference than at last note.

Sept. 28, 1902. Since last note knee has been quite painful and there has also been some pain in other knee and a sensation of slipping. Right knee as seen today shows no increase of joint fluid. The thickening of the synovial membrane in the lower part of the joint quite apparent, and motion is made very gradually with only 45° of flexion from a straight line possible.

December, 1902. Incision made through the inner side of the right knee. Large fringe removed from ligament over the line of the joint. No other fringes on inner side but a small lipoma, the size of a pullet's egg, removed through a second incision through the outer side of the joint. Upon this was a smaller one attached to the parietal wall. The left knee shows a similar condition. Recovery from operation has been uneventful.

The specimen removed consisted of two separate outgrowths: the first a flat, vascular fibrous tab of tissue, 2 by 5 cm., which was attached to the synovial membrane beneath the patella; the second a fatty lobulated mass, quite vascular, but not dark in color, 6 by 3 cm., which was attached to the synovial membrane by a narrow pedicle. Microscopic examination of the second showed a thin cortical layer of connective tissue, densely infiltrated with small, round cells, with the appearance of granulation tissue. The remainder of the specimen consisted of adipose tissue through which ran strands of fibrous tissue, staining feebly, and usually in the immediate neighborhood of vessels, the amount varying directly with their size. These vessels are very numerous, and endarteritic changes are the rule.

CASE V. A. R. Patient is a nurse thirty-three years old, who has been troubled for one and one-half years with a swelling of the left knee. This has not been constant, but came on at intervals without any apparent cause. The frequency with which it was causing trouble has been increasing. The family and personal history were negative, and there has been no injury to the knee other than hard use at her occupation.

Examination.—The left knee is much swollen, 3 cm. greater in circumference both over the lower border of the patella and above that bone; this swelling being due to an increase of fluid in the joint. Motions not restricted except in the extreme of flexion. No increase of surface temperature; no redness. No interarticular thickening could be felt.

Operation, Jan. 24, 1903. Incision 6 cm. long over inner aspect of joint. Capsule not thickened or abnormally vascular. Membrane not congested or hypertrophied, except in the place to be mentioned. About 6 oz. of clear, straw-colored fluid evacuated.

On lifting the patella up, with the knee flexed about 20°, a good-sized synovial fringe presented, coming from the membrane just in front of the anterior-inferior border of the patella, and dropping down between it and the femoral condyles, and probably between the tibia and femur. The free end of this was quite congested and granu-

lar in appearance, and the whole mass of tissue was perhaps 2.5 cm. in length by from .7 to 1 cm. in width at its base before it was cut off. There was a smaller though a much swollen one over the external condyle of the femur. In consistency the growth felt very soft, as though more fatty than fibrous. Otherwise the joint membrane and the cartilages and bones seemed normal in appearance.

Capsule closed with interrupted silk, and skin with silk-worm gut. Dry dressing and plaster of Paris splint.

Specimen consists of a round mass .3 cm. in diameter, and somewhat flattened. It is gray to reddish in color, and is covered with little projecting tabs of a fatty consistency.

Microscopically the cortex of growth consists of a narrow layer of small, round cells closely packed, inside which is a narrow, irregular layer of connective tissue containing numerous thick-walled vessels. The remainder of the section consists of normal adipose tissue, interspersed by bands of connective tissue of varying widths, while scattered throughout are thick-walled vessels in islands of connective tissue, some of the smaller with obliterated lumina.

CASE VI. E. M., aged twenty-four years. On Oct. 8, 1900, twisted the right knee while playing football. On account of effusion was kept in splint four weeks. Again in November a similar accident, which was slower in recovery.

April 12, 1901, slipped, twisting the same knee; effusion with slight tenderness on fibular side. No history of "catch" in joint. Splint for three weeks and then the elastic bandage. About the middle of May there was perfect motion and no effusion. On May 20, while stepping backwards, felt a sudden, sharp pain in the joint when weight was put on it. Effusion; motion free without pain. On manipulation in flexion felt something slip in the joint; then on standing erect no more pain. On crutches until four days previous to June 24, 1901. Effusion has disappeared very slowly. No "catch" at any time and no pain except on standing at the time of last injury.

Examination.—Right knee slightly swollen and about 40° of motion in flexion is allowed, the limitation being due evidently to the fixation of adhesions. From history condition probably represents bruise of semilunar cartilage without displacement of this at time of last injury. To consider conservative and operative treatment.

Because of repeated attacks of synovitis an operation was decided upon, and the joint was opened on both sides in November, 1901. Over the inner side was found a partially detached internal semilunar cartilage which was removed. Several small fringes were also removed, and through the incision on the outer side of the joint a small fibro-fatty tumor the size of an English walnut was excised. This was sessile and attached to the parietal wall of the joint. Convalescence was uneventful, and now, over one and one-half years from the operation, the function of the joint is normal and there are none of the old symptoms.

Specimen removed consisted of several large congested fringes, many of them 1 cm. in diameter, and a fatty mass 3 cm. in diameter, and the inner end of the internal semilunar cartilage.

Examination of the fringes microscopically showed a fibrous capsule irregularly infiltrated by small round cells which in limited areas are densely packed. Within is adipose tissue, into which at intervals project from the capsule irregular bands of fibrous tissue. Throughout this tissue are scattered many blood vessels, the larger ones with thickened walls, the smaller, which are much more numerous, nearly or quite obliterated.

CASE VII. L. C., female, thirty-four years old. Entered Carney Hospital June 22, 1902. Ten months previously noticed a swelling in lower anterior aspect of knee joint, which gradually increased. There was no locking but a slipping sensation in joint, and at night leg was tired and joint stiff. There was no pain. No treatment until two months before admission, when leg was held fixed in plaster.

Examination showed in the region of the semilunar cartilages of the right knee a firm, fibrous mass which rolled under the fingers. The part which fell between the bones was very gristly in character, the rest of a

softer consistency. No limitation of motion. Left knee normal.

Operation, June 23. Through an incision over inner aspect of joint an irregular sessile mass protruded, the attachment to the synovial membrane was divided; wound closed and leg fixed in plaster.

On discharge July 5, motion of knee was normal and swelling was very slight. In October, 1902, the joint was symptomless and its function normal. The specimen removed consisted of a very vascular mass of grayish-

FIG. I. — Lipoma arborescens.

FIG. II (Section of Fig. I).

red to brownish tissue 5 by 8 cm., and about 2 cm. thick. It consisted of several fringelike processes, and was attached to the synovial membrane by a very short pedicle, 1.5 cm. in diameter, and its consistency varied from fatty to tough, the latter being characteristic of that part which came in contact with the bony surfaces of the joint.

SUMMARY OF SPECIMENS.

In general, the clinical picture presented by these cases is that of a more or less swollen joint, without any signs of acute inflammation and most commonly without even any excess of fluid. The patient complains of imperfect function sometimes with and sometimes without pain; more often the latter. They also sometimes complain that the joint "locks"

FIG. III. — A section of a lipomatous tumor occurring elsewhere than in a joint, showing the histological difference from the lipoma arborescens.

in a partially flexed position, and can be straightened only after considerable effort.

The lipomata vary greatly in size, reaching often that of a good-sized hen's egg. In shape they vary also from round, regular masses, studded with small tabs of fatlike tissue, to irregular masses, with long fingerlike processes, which are often bulbous at the distal ends. They are attached to the synovial membrane by a pedicle, usually slender, which on cross section is found to consist almost wholly of blood vessels lying in a mass of small round cells. In consistency they vary from a soft, fatty to a tough, fibrous condition, both varieties often found in the same specimen, while the color varies from a yellowish-gray to a dark purplish-red. They are very vascular, and after removal shrink to a great extent. Microscopically the cross section of any of these masses shows a cortex of varying thickness of closely packed round cells, often grouped in round clumps, separated by strands of fibrous tissue infiltrated to a less degree by similar cells. Within this outer layer is one of varying thickness of fibrous tissue, but little infiltrated with small round cells, and containing many blood vessels with thickened walls. The bulk of the mass consists, however, of normal adipose tissue, through which run bands of varying width of fibrous tissue, staining more or less feebly, and often showing signs of granular degeneration. Scattered throughout the adipose tissue are very numerous blood vessels, all with thickened walls, carried in the smaller to the extreme of obliterating their lumina, lying in small islands of fibrous tissue.

The occurrence of this condition has been recognized for some time in the pathological textbooks, but has received very little attention in the surgical textbooks. German authors have described it more often than any others, and have regarded the presence of these joint lipomata as representative of one of two conditions, as a rule, namely, synovial tuberculosis or arthritis deformans. In this way Ziegler (in his *Special Pathology*, p. 2711) refers to these lipomata arborescentia, and regards them as the result of a fatty metamorphosis of the normal synovial villi.

Coplin, in his *Manual of Pathology* (pp. 242 and 535), says that he believes lipoma arborescens to be simply a step farther than "cloudy swelling" in the process of fatty degeneration, analogous to the same process in the kidney. He believes it is caused by (1) anemia, (2) necrosis and caseation, (3) bacterial toxins, (4) embolism, (5) infections, etc. According to Coplin these degenerations develop in sub-synovial or subserous tissues, and push their way into the neighboring cavities.

Dalafield and Prudden, in their *Pathology* (pp. 317 and 779), refer to the lipoma arborescens as pushing into the joints as "tufts" of synovial membrane.

Hektoen-Riesmann in the *American Text Book of Pathology* simply advance the old theory that these growths are signs of some underlying cause, as tuberculosis or osteo-arthritis.

Haeckel reviewed the literature up to 1888, and described two new cases of lipoma arborescens in his own experience. This article was entitled "Lipoma Arborescens," and appeared in the *Centralblatt für Chirurgie*, April 28, 1888; later still, in the *Allg. Chi. für Path. und Therapie* (8 Auflage, p. 706), Billroth has another contribution to this same subject.

Stieda, in a carefully written paper on lipoma arborescens of the knee, appearing in the *Beitrag für klin. Chir.*, xvi, p. 285, 1896, gives an exhaustive review of the literature on the subject up to that date. Including his own two cases, he mentions thirteen, in ten of which the knee was involved, in two the shoulder, and in one the hip.

The first case on record is one described by Gætz in his *Dissert. inaug. Halle.*, 1798.

The name "lipoma arborescens" was first given to the condition by Joh. Müller in his "*Ueber den feineren Bau und die Formen der krankhaften Geschwülste*," while the first suggestions regarding its etiology were made by Volkmann in the *Centralblatt für Chirurgie* for 1885. He classified lipoma arborescens of the joint, with other chronic enlargements, as a condition not of necessity primarily tuberculous, but developing into it.

König, writing in 1885 and again in 1895, considered the condition as a manifestation of tuberculosis only, but finding later a similar condition in cases of arthritis deformans, he at first tried to distinguish them, and finally admitted the great difficulty in so doing.

Schmolek, in 1886, reported two cases, both of long standing, in which at the time of operation a fresh tuberculous lesion was found, from which he concluded the condition to be one of lipomacie of the joint favoring the invasion of the bacillus of tuberculosis.

Haumann in his *Dissert. inaug.*, at Bonn, in 1887, reported a case in which the condition was associated with a chronic rheumatoid affection. He too thought the structure favored the presence of tuberculosis.

Israel reported a case following trauma, in which no focus of tuberculosis was found.

Riedel in the *Archiv. für klin. Chir.*, vol. xli, 1891, mentioned a case in the knee joint following a healed periarticular tuberculosis. No focus was found at time of operation or in the specimen removed, but there was a subsequent exacerbation of the disease. The same was true in a case involving the shoulder,

which was afterwards involved by a process starting in the humeral head. He considered that the condition developed from mild inflammatory conditions, as tuberculosis and arthritis deformans.

Schüller, writing in the same publication, vol. xlv, 1893, noted the fact that small tuftlike growths from the free surface of the synovial membrane are not pathological but are found even in the newborn. The pathological cases were to be considered not as tumor formations but as simple hypertrophies, the result of chronic inflammation.

Modlinski, writing in the Russian *Medizinskoje Obosrenije*, No. 20, 1891 (as quoted by Stieda), reported a case of lipoma arborescens of both knees, in which a local and general tuberculosis was found.

Sokoloff in the *Chirurg. Itscheskij Westnick*, 1893, 2 and 3, and the same year in Volkmann's *Klinische Vorträge N. F.*, No. 81, September, 1893, reported one case in the knee in which no tuberculous focus was found, one in which such a focus was found, and one in a case of a syringo-myelic arthropathy of the shoulder, with enlarged joint cavity, atrophied humeral head, and luxated bone. From this last case he advanced the theory that a condition of negative pressure in a joint was also an etiological factor in the growth of lipoma arborescens, as favoring the hypertrophy of fatty tissue.

Of Stieda's two cases, the first affected the knee. It was of long standing, with an old history of injury. Aspiration of the fluid in the joint being unavailing, the joint was resected and a complete recovery resulted. The second case was an old museum specimen of a hip involved in a condition of arthritis deformans, showing a marked lipoma arborescens of the joint. Stieda's conclusions are as follows:

(1) Lipoma arborescens occurs in a number of chronic joint affections.

(2) It is not a lipoma in the sense of being a "new growth," but is merely a hypertrophy of normal pre-existing tissue.

(3) Its etiology is a chronic inflammatory condition of the joint, arising usually from tuberculosis or arthritis deformans and possibly a condition of negative pressure in joint.

(4) Pathologically it is an hyperplasia and fatty degeneration of pre-existing synovial tabs, to an extreme degree.

(5) Histologically the appearance is that of a typical chronic inflammatory condition, with, in addition, a specific appearance in case of tuberculosis.

(6) In an unopened joint, diagnosis is not certain, the swelling, tenderness, limitation of motion and ability to palpate not being absolutely diagnostic.

(7) Prognosis of spontaneous healing and recovery of joint function unfavorable.

(8) Treatment: arthrectomy (erosion) or when tuberculosis is present, resection of the joint.

With these conclusions our observations would, in the main, agree. Where we should differ from the author above quoted would be in giving tuberculosis relatively a less important place in the etiology, and we should urge the importance of the absence of the clinical evidence of joint disease as leading to the diagnosis of a non-tuberculous condition, and encourage exploration of the joint where any doubt exists as to the nature of the pathological process.

SUPPURATION OF THE FRONTAL, ETHMOID, AND SPHENOID SINUSES.

WITH BRIEF REPORT OF THE TREATMENT OF TWO HUNDRED AND THIRTY-SEVEN CASES.

BY EDGAR M. HOLMES, M.D., BOSTON, MASS.

OWING to the often severe and distressing symptoms, as well as to their etiological importance in the production of pathological conditions in the ear and throat, the study of the diseases of the accessory sinuses of the nose is one of the most interesting and important with which we have to deal. This subject has received much attention during the last few years, and although many points are still unsettled and under discussion, a great deal has been accomplished, and we are given much information in regard to the etiology, symptoms and treatment of this class of cases. Many cases of persistent and severe ear and throat difficulty are now known to be due to disease of these structures, and many can be greatly relieved by removing or relieving these exciting causes. It is my purpose in this paper to consider the affections of the cavities situated at the superior portion of the nose, namely, the frontal, the ethmoidal and the sphenoidal; and in a general way to report 237 of these cases treated in my office.

As the drainage plays such an important part in the etiology as well as in the treatment of all the sinuses, I deem it advisable to briefly review their anatomy. As a whole, they occupy much of the space between the nasal and naso-pharyngeal cavities below and the cranial cavities above, and although they vary considerably in extent and in the position of their natural openings into the nose, yet these variations have limitations within which we may expect to find the great majority of cases.

The frontal sinus usually develops between the tables of the frontal bone, over and between the eyes, above the root of the nose. There is almost always a thin plate of bone which separates the cavities on either side. This is not always in the median line and it is sometimes perforated. These cavities vary greatly in size, and one or both may be wanting. Although there seems to be much difference of opinion, the general belief is that they begin to develop at about the second year by the upward extension of the ethmoid cells. At about the seventh or eighth year they can be recognized as a distinct cavity above the root of the nose. They gradually increase in size, and at the age of puberty may be quite extensive. It is claimed by some anatomists that they continue to increase into old age. This is of little importance so long as we bear in mind that at all ages they are subject to great variations and may be separated from important structures by only a mere shell of bone. This is also true in dealing with all of this group of cavities. The shape or prominence of the supraciliary ridge is of little aid in determining the shape or size of the cavity behind it, which in some cases extends over the orbital roof as far as the external angular process, and occasionally nearly as far back as the optic foramen. The frontal sinus often communicates with the anterior ethmoidal duct, either directly into the middle fossa anteriorly or after having joined the infundibulum. The ethmoid sinuses are divided into various groups by different an-

atomists, but from a clinical standpoint it is sufficient to divide them into two groups, an anterior, which communicate with and drain into the middle meatus of the nose, and a posterior group, which communicate with and drain into the superior meatus above the middle turbinate. The lateral mass of the ethmoid bone forms by its outer surface the greater portion of the inner wall of the orbit and by its inner surface the upper outer wall of the nasal cavity. The body of this mass is made up of thin trabeculae of bone bounding variously shaped and sized cavities, the whole structure resembling that of a sponge. There is no regularity in the number or size of these cells, and there is no relation in the amount of space occupied by the two groups. The anterior group may have several openings into the middle meatus, and may also communicate with the posterior group. They are closely associated with the floor of the frontal sinus and the naso-frontal duct. At times one of the cells develops upwards and forwards and forms a prominence upon the floor. This has been called the *bullula frontalis*. Occasionally some cells extend into the roof of the orbit, below the frontal sinus, and may extend as far back as the optic foramen. At the anterior part of the lower border of the lateral mass of the ethmoid is a prominence containing one or more cells called the *bullula ethmoidalis*. At times there are cells in the anterior portion of the middle turbinate which may be so large as to block the whole superior portion of the nasal cavity.

The posterior group of ethmoid cells may extend below, encroaching upon the maxillary sinus, and occasionally the sphenoid body contains an ethmoid cell of considerable size. At times they occupy the greater portion of the lateral mass of the ethmoid and again only a small posterior portion. The general relation and great variation of the ethmoid cells makes it evident that any suppurative process may cause pressure and produce symptoms pointing to the frontal maxillary and sphenoidal regions.

The sphenoid sinuses, like the other sinuses, vary in quite a marked degree. They occupy simply the anterior part of the body of the sphenoid bone or they may extend even into the baso-occipital behind, into the base of the great wings laterally, and into the lesser wings superiorly. The larger the cavities, the thinner must be the bounding walls. As these walls are in contact with many important structures which without great care might become injured during operations, I will give here a few of the more important relations. Above the cavity approaches the cranial cavity, and is covered from before backward by the root of the lesser wing, the olivary process and the sella turcica. Upon these rest the olfactory peduncle, the optic commissure, the pituitary body, and when the cavity extends far back the pons varolii. The optic nerve and the ophthalmic artery are situated near where the roof joins the external lateral wall. The roof is at best very thin, and when diseased may even be perforated. The anterior wall which forms the posterior portion of the roof of the nasal chamber is nearly vertical at its upper part and inclines backwards below where it meets the floor. This wall is very thin, and through it the cavity communicates with the sphenoidal fossa of the nose.

The external lateral wall, often very thin, is de-

pressed from the cranial side for the internal carotid artery and the cavernous sinus posteriorly, anteriorly it is the inner boundary of the sphenoidal fissure through which pass the third, fourth, the ophthalmic division of the fifth, and the sixth cranial nerves and the ophthalmic vein. There is a septum of bone, usually complete, which separates the two cavities. This occasionally deviates so that at times there is marked inequality of the two cavities. It sometimes happens that one cavity is nearly behind the other, and I have seen a specimen in which one cavity was posterior to the other, and communicated with the nose only through the anterior cavity.

The lining of all the accessory sinuses is a thin mucoperiosteal membrane, with a layer of ciliated epithelium upon the surface.

The position of the outlets of the various sinuses is of great importance, in both enabling us to make a diagnosis and to treat the disease conditions found.

The infundibulum, which in about half of all cases is joined by the naso-frontal duct, opens into the anterior portion of the middle meatus between the ethmoid bulla and the uncinate process, under cover of the middle turbinate body. Where the naso-frontal duct does not join with it, it opens in front of the infundibulum directly into the middle meatus. Under these conditions it is short and straight and more nearly vertical. Neither of these openings can be seen, as they are covered by the middle turbinate. A small probe can usually be passed through these ducts, and often is an aid in diagnosis. It is not rare for one or more of the ethmoid cells to communicate directly with the middle meatus.

The posterior ethmoid cells and the sphenoid cavity open above the middle turbinate, the ethmoid into the superior meatus, and the sphenoid into the spheno-ethmoidal recess. They are much more easily explored by the probe than the anterior group. In a large number of cases there are two or even three openings from the posterior ethmoid cells, one opening is often situated in the small groove which frequently lies just above the superior meatus. The sphenoidal sinus communicates through a single small opening at the superior posterior portion of the outer wall of the nasal chamber. This opening varies considerably in size and position. In relation to the sphenoid cavity, it is nearer the roof than the floor, at times immediately below the roof. The olfactory cleft is usually so narrow that the opening cannot be seen. Even when the middle turbinate has been removed the opening may be located so far out or the superior turbinate may project so far that direct inspection is impossible. I have been able to see the opening in several cases where the middle turbinate had undergone atrophy, and in a few cases where it was near the septum, and where there was an unusually large olfactory cleft.

After this slight anatomical review, it is easy to understand how so many and often times extensive cavities may become infected by various bacteria, and when the resulting inflammations are set up how liable the inflammatory products are to infect the other cavities and to cause pressure when the openings become blocked by swelling of the mucous membrane lining them.

Anything which lowers the general vitality, as

overwork, excess in eating and drinking, lack of fresh air and exercise, exposure to cold, chronic diseases, like diabetes, nephritis, syphilis, cardiac and pulmonary disorders, and malaria, may be lowering the resistance of the nasal mucous membranes to the attack of the various bacteria which are so frequently present and act as etiological factors in the production of suppurative inflammation of the accessory sinuses. During the course of such acute diseases as scarlet fever, measles, diphtheria, typhoid fever, pneumonia, influenza, tonsillitis and rheumatism, there is often an inflammatory process set up in these cavities. Exposure to irritating dust and vapors is liable to cause local inflammations which easily become infected. Foreign bodies accidentally introduced into the nose or intentionally placed there to stop hemorrhage or give support to a fracture may, by their mechanical irritation and obstruction, cause an inflammatory process in one or more of the accessory cavities. Tumor growth, syphilitic gummata and ulcerations, and perhaps local tuberculosis, as reported by Lapalle, although Howard and Ingersoll failed to find tubercle when looking especially for it, may also act as etiological factors. Near thickly settled communities, where so many are constantly spitting collections of pus upon the street, which during dry and windy weather is soon reduced to powder, contaminating not only the air outside but filling every house, we have a very important source of infection, and almost every rhinologist has observed the frequency of acute suppurative processes following such spells of dry, windy weather. This is especially noticeable during cold winter weather, whenever the ground is free from snow.

E. Fränkel and Weichselbaum were among the first to direct our attention to the organisms associated with suppurative disease of the accessory cavities. The Klebs-Loeffler bacillus has been found by E. Fränkel, Weichselbaum, D. Mochowsky, Pearce and others. The pyogenic organisms, the various streptococci and staphylococci, have been found and reported by many observers. The bacillus of influenza has been demonstrated by Weichselbaum in 90% of autopsies on patients dead of influenza. The onset often coming, as it does during acute illness or following a rhinitis, is liable to escape the patient's attention, and as many cases are of months and perhaps years' duration when they come to the physician's care, it is not remarkable that it is impossible to find the etiological factors in so many of them. Sixty-one of my cases consulted me for deafness, some with and some without tinnitus, and gave no clue to the sinus trouble either in the past history or present symptoms except the general statement that they had catarrh. Eighty-three attributed the beginning of their trouble to an attack of influenza. Seventeen cases had had constant catarrh since attacks of diphtheria. Twelve patients claimed to have had no trouble until after a severe injury to the nose. Eleven were of the opinion that they had been free from nasal symptoms until after an attack of scarlet fever. In eight cases no symptoms were complained of, or at least remembered, until there was cough and other signs of pulmonary tuberculosis. Only seven cases were attributed to syphilis, although twenty-three had at some time been afflicted by this disease.

Five thought that a prophylactic dose of diphtheritic serum was responsible for all of their trouble, and three that vaccination was surely the cause. I saw one case where a left sphenoid and posterior ethmoid suppuration started during an attack of typhoid fever, and persisted in spite of treatment until the anterior portion of the sphenoid was removed and the cavity curetted. I cannot prove that these cavities were healthy before the fever, but there were no symptoms, and I had treated one patient for a suppuration of the right ear for two months before the onset, and had repeatedly examined the nose and naso-pharynx. Culture taken of this case showed streptococcus and typhoid bacillus. In the remainder of this series, numbering thirty, no cause was given, and when we consider the great number of cases which do not give symptoms of sufficient severity to direct attention to the nose, it is evident that many of these could have existed prior to the existence of the supposed cause. For the same reasons autopsies in certain diseases can only demonstrate the presence of sinusitis, and not prove the disease as the cause of the suppuration, which may have been present prior to its onset.

Our knowledge of the pathology of the accessory sinuses has been derived from both postmortem examinations and clinical observation, and, although there are marked differences of opinion as to the existence and frequency of the pathological conditions found and reported, the majority of pathologists as well as clinicians are agreed that the changes are those found in mucous membranes upon other parts of the body. Many and perhaps the majority of all acute inflammations tend to subside without treatment, and if the symptoms have not been very severe or alarming in character the patient has not consulted a physician. Inflammation of the frontal sinus, if not so severe as to cause ulceration, will in the great majority of cases subside. The outlet, unless blocked, is so situated as to give good drainage and probably only a very small percentage becomes chronic. The pathological conditions found vary according to the severity and duration of the disease, the ease with which the secretions are evacuated and the resistance of the membranes attacked. There may be simply congestion or inflammation with round-cell infiltration, or there may be ulceration of the mucous membrane with granulation tissue, polypoid or cystic formations, or even caries and necrosis of the underlying bone. Pressure in a retained cavity may distend its walls or cause necrosis and rupture through. In this manner the various groups of cells may become joined or fistulous openings may take place into the orbit, cranium, nose or naso-pharynx. A free opening into nose or naso-pharynx may so drain the infected cavity that the trouble subsides without any other interference. When there is a discharge of pus over the mucous membrane in the nose or throat for any length of time, it is usually found to be puffy, of a more or less deep red color, and often presenting a glassy surface. In cases of long duration there is often an atrophic condition, and there is still much discussion as to whether the atrophy or the sinusitis is the primary lesion. During the last three years there has much been added to the side of the sinusitis as the primary

affection. In 14 cases I had to deal with atrophy accompanied with the formation of foul-smelling crusts, and, although I cannot positively say whether the sinusitis or the atrophic condition was primary, I can say that in 11 of these cases after relieving the sinusitis the crust formation ceased and with it the odor. Two of these have remained apparently free for over three years and four for over two years.

The direct irritation of the pus may cause inflammation of the naso-pharynx, and by extension produce inflammation in Eustachian tube and middle ear. This may be found in various degrees of intensity. The pus when it reaches the pharynx and the larynx may produce marked inflammatory processes with the accompanying symptoms. In one of my sphenoid cases there had been necrosis through roof. There was no normal outlet to be found and after drilling through floor pus fairly poured out. I collected two fluid ounces, showing, as did some of the symptoms, that there was likely an epidural abscess.

(To be continued.)

Clinical Department.

MASSACHUSETTS GENERAL HOSPITAL.

CLINICAL meeting of the staff, held Dec. 12, 1902, in the Treadwell Library, the President, Dr. C. B. PORTER, in the chair.

DR. J. B. BAIN reported briefly a case of blank cartridge wound of the hand, from which tetanus bacilli were isolated. The wound was freely incised and all affected tissues removed. No tetanus developed.

DR. S. J. MIXTER: I remember that when our attention was so strongly called to this subject two or three years ago on account of the tetanus cases, I insisted that all cases brought to the accident room with cartridge wounds should have the most careful attention, that the injured tissue be cut out and the wound thoroughly cleansed, and if the patient refused to take ether and have the wound attended to in this thorough way he should not be treated at this hospital. I think that this is necessary. No case has been worked up so carefully as this, but the treatment outlined by Dr. Bain is the treatment used in the accident room.

DR. H. H. A. BEACH demonstrated the following cases:

CASE I. ENLARGED THIRD LOBE OF PROSTATE GLAND; CHRONIC RETENTION; SUPRA-PUBIC EXPLORATION; REMOVAL OF THIRD LOBE AND THREE CALCULI.

The patient was a man of fifty-five years, with a history of arthritis at twenty. Six years ago had frequency of micturition, gradually increasing, with pain; slight incontinence at night. Three years ago had three pints of urine drawn by catheter, and was confined to bed for five weeks. Since then has never been able to pass urine except by catheter No. 8. Four weeks ago he began to have pain in passing catheter, which lasted for some hours afterward. For two weeks pain was constant, sharp and shooting from the neck of the blad-

der to the glans penis. By the rectum the prostate was not tender, nodular, or enlarged sufficiently to account for symptom. A No. 10 catheter passes easily into the bladder, evacuating foul, cloudy urine. Under ether, a stricture found and dilated to No. 32.

Constant drainage and the bladder washed out with borate solution. The urine became clear, but the pain at the neck of the bladder returned, and the drainage was discontinued, the pain after catheterization increasing. Suprapubic cystotomy was done, and a valvelike process of the prostate found obstructing the inner opening of the urethra. It was excised, and three small calculi removed. For the free bleeding from the fresh surface left after excising the obstructing lobe, a solution of adrenalin was applied on a piece of gauze held by forceps, with the effect of immediately blanching the tissues and controlling oozing. His progress has been uneventful; the bladder wound has closed. He can retain his urine five or six hours, when he uses the catheter, without pain. He is beginning to pass urine without catheter.

CASE II. CANCER OF PYLORUS; OBSTRUCTION TO PASSAGE OF SOLID FOOD; GASTROENTEROSTOMY WITH THE MCGRAW LIGATURE.

Patient a man fifty-eight years old. First noticed a tumor in the epigastrium between eight and nine months ago. Distress after eating solid food began two months before that. Stomach contents show no hydrochloric acid. In patient's epigastrium, capacity 1,400 cc., is felt a hard, slightly irregular, movable mass 8×5 cm., the lower border at about the level of the umbilicus, left border just to the left of the median line.

Vertical incision of six inches through the right rectus muscle. Tumor about the size of an egg, surrounding the pylorus. Enlarged, hard glands in gastro-hepatic omentum, retro-peritoneal region and adjoining mesentery. A loop of jejunum brought up to greater curvature of stomach near pylorus and fastened with a row of Lembert silk sutures, two and one-half inches long. Just above this a McGraw rubber ligature inserted joining stomach and intestine, taking in the right, one and three-quarter inches of each organ, then protected by a second row of silk Lembert stitches. He had very little constitutional disturbance from the operation, the temperature rising 100.8° once only immediately after the operation. He was fed with nutrient enemata for nine days and then beginning with small quantities of milk and lime water, his diet was gradually increased. Wound solid and stitches out on the seventh day. Between the tenth and fourteenth day after operation he had some vomiting, and finally ejected the ligature. After that his gastric disturbance quieted down, and he has taken more or less solid food every day and digested it, relieving the embargo upon a general diet. The case is reported as contribution to the literature of the McGraw rubber ligature, recently brought to the attention of the profession.

CASE III. — BILIARY FISTULA FOLLOWING CHOLECYSTOTOMY; PERSISTENT SYMPTOMS OF BILIARY OBSTRUCTION; CHOLEDOCHOTOMY; COMPLETE RELIEF.

The patient, a negro woman, thirty years old, en-

tered the hospital with a fistulous opening about an inch below the right costal border. This had opened and closed irregularly during the past year and a half, following an operation, performed in Tennessee, for the removal of two gallstones. The drainage tube had remained five months.

When the fistula is closed the patient reports that she has "yellow eyes, dark movements of the bowels and urine," when it is open she has "clear eyes, light-colored movements and urine."

She has frequently abdominal colic, with pain in the right shoulder, and is disabled for work. During the past week the fistula discharged bile very freely. The scar of the operation was solid, and a firm mass, the size of a hen's egg, could be felt below it in the direction of the umbilicus.

Through an incision of four inches parallel with the costal border and below the old wound, the peritoneum was opened.

Many adhesions were found, masking the gall bladder, the inferior surface of the liver and adjoining intestines nearly to the median line. After a careful exploration of the adhesions in the direction of the common duct, a hard body could be felt by carrying the finger beneath them. The duct, however, could not be exposed from its superior surface without damage to adherent intestine, and other structures, nor could I push the stone into the intestine. Therefore, after carefully walling off the general peritoneum cavity, I opened the duodenum and felt the stone from within, then cutting into the common duct, released a stone the size of a marble, not faceted. The wound in the duodenum was then closed with silk Lembert stitches. The abdominal wound closed and drained. Nutrient enemata were used for the first few days and convalescence was uneventful. She was discharged well, with a soundly healed wound, in seven weeks.

CASE IV. CHOLELITHIASIS; CHOLEDOCHOTOMY; COMPLETE RELIEF.

The patient, a man thirty-nine years of age, two years ago had for three weeks diarrhea, nausea and vomiting, dull pain in epigastrium and jaundice. The urine dark and stools clay-colored.

Seven months later, a chill with excruciating pain in epigastrium shooting through to the back, under the shoulder-blade, vomiting and profuse perspiration. With morphia pain was relieved in about eight hours. He was jaundiced for a few days, had dark urine and clay-colored stools. In a year and a half, he had about twelve similar attacks, though not as severe. Never disabled for more than a day. Five months ago had a severe attack, the pain lasting seven or eight hours; since then, mild attacks every ten days or so. The last, one week ago, pain occurred in the afternoon. He vomited, and with the aid of morphia he was relieved in the course of four hours. He felt poorly the next day and was jaundiced. Upon entering the hospital he was feeling well. There was slight general jaundice, but no tenderness of the gall-bladder region. The upper border of liver dulness at the fifth rib. Upon full inspiration, the liver could be felt one finger's breadth below the costal border.

Incision of five inches into peritoneal cavity below the right costal border. Transverse colon, gall bladder and small intestine were adherent in

a solid mass. By cautious exploration with the finger from the under side of the mass, a stone could be felt in the upper part of the common duct. By manipulation the stone was worked back into the gall bladder, only a small area of which was visible between adherent coils of gut. The stone was worked along to that point and held firmly between the thumb and forefinger. The gall bladder was opened and a stone the size of a marble removed. Several smaller stones were fished out with a scoop. No evidence of malignant disease was detected. A glass drainage tube was tied in the gall bladder, from which flowed some ounces of bile, and the abdominal wound closed. On the first and second days after the operation he vomited bile several times. His tube was removed on the seventeenth day, convalescence was without incident, and the wound was solidly healed one month after the operation, when he was discharged well.

CASE V.—PROLAPSE OF THE RECTUM;
OPERATION; CURE.

Patient was a woman fifty-eight years old, the mother of ten children.

She had no urinary symptoms, but was usually constipated. Two years ago the rectum showed a tendency to protrude from the anus, which has become much distended, and now permits a prolapse of five inches. This is easily brought about by standing, walking, during defecation and micturition. She has always been able to reduce it by crossing her legs, or by lying down. She has a slight cystocele and the uterus is much atrophied.

An oblique incision of three and a half inches through the abdominal muscles in the left iliac region as for artificial anus, through this the sigmoid flexure was caught up and hauled tight so that there could be no protrusion at the anus. The intestine was then stitched by a double row of Lembert sutures of chromic catgut to the peritoneal borders of the wound. The muscles were then united over the intestine in layers, the skin with silkworm gut sutures, the latter were removed on the fourth day, the union perfect. The bowels were not moved as usual after a laparotomy. She had soft solids on the eighth day, and house diet on the ninth day. Bowels moved spontaneously on the eleventh day without any prolapsus.

Discharged well.

Reported at the hospital three months after in as good condition as at time of discharge.

CASE VI. HYDRONEPHROSIS; OPERATION.

Patient was a woman thirty-one years old. Her health had been good until three years ago, when she had an attack of severe pain under the right costal margin. At that time a decided lump was felt in the region of the gall bladder, which was tender on pressure. The size of the mass seemed to bear no relation to the quantity of urine passed. She had vomiting, jaundice and clay-colored stools. For six months she was ailing more or less. Eight days ago a similar pain was felt and the mass under the ribs reappeared. For two days she vomited and was jaundiced, the stools clay-colored. The jaundice has disappeared, the pain remains, but is no worse and the size of the mass has diminished.

Upon examination the abdomen was not distended. Just below the costal border is a mass of the size and shape of a pear, which is smooth and moves with respiration, being apparently connected with the liver. It is slightly tender upon bimanual pressure. No jaundice. Pelvic examination negative. On the day after entrance no pain or symptoms.

During the next four days the temperature rose at night and the mass enlarged to size of a grape fruit, fluctuating from front to back through the loin and evidently involving the kidney. The abdomen was opened by an incision of five inches through the outer border of the rectus muscle, extending downward from the free edge of the liver. The tumor was found to be retro-peritoneal. The left abdomen was explored for a kidney, and one found in normal position. The gall bladder was normal, also the appendix. The intestines were then pushed to the left side with a mass of gauze, and the peritoneum opened for about four inches outside of the ascending colon, reflecting the peritoneum, so as to expose the kidney and ureter of the right side, the pelvis of the kidney was distended to the size of an orange and the organ itself displaced downward for three inches. Following the ureter downward the upper one and one-half inch was much distended, then a sharp kink was found with an S bend, and below this point the ureter was collapsed. On pushing the kidney up into normal position, the bend disappeared, the pressure was relieved and the collapsed ureter became suddenly filled with fluid, and the tumor as rapidly diminished. With gentle pressure one half of the contents of the kidney pelvis passed downward in a few minutes. The kidney was now turned so that its convexity faced downward, toward the ureter, which provided for the most complete drainage of its interior and was then fixed in that position by some sutures to the eleventh and twelfth ribs. By including the lower part of the capsule, the kidney was suspended in a slinglike support, completely obliterating the kink. A gauze handkerchief was packed beneath it, until the adhesions should be firm and the wounds closed. In a week the gauze was removed. Temperature was normal, urine about 40 oz. daily.

In twenty-five days after operation no mass could be felt in the loin, the urine was normal and only a small granulating area in the scar.

Discharged relieved.

(To be continued.)

Medical Progress.

PROGRESS IN PUBLIC HYGIENE.

BY SAMUEL W. ABBOTT, M.D., BOSTON.

(Concluded from No. 11, page 287.)

DISINFECTION.

Further experiments have been made and reported upon by Calmette and Hautefeuille¹¹ upon the efficiency of the Clayton apparatus for the evolution of sulphurous acid in the disinfection of ships. The experiments were made upon a ship of 1,200 tons at Dunkirk, France. Recent cultures of

¹¹ Rev. d'Hygiène, October, 1902, p. 865.

typhoid bacilli, cholera and plague were employed for the experiments, part of which were conducted in the hold of the ship and part in a stateroom on deck, having two berths furnished with mattresses. In all bands of flannel were used and impregnated with the disease germs, some of which were introduced dry and others moist. Control samples were kept on deck outside the influence of the gas. The machine was put in operation at 10.55, and at 1 P.M. the gas in the hold amounted to 5% of the air.

At the inlet of the gas the percentage was as high as 15%.

In the cabin or stateroom the samples were placed upon the mattresses in the berths, and some were covered with a coverlid folded double. The gas in this room at the level of the berths rose to 8%. After stopping the action of the gas, the germs were allowed to remain exposed two hours and were then removed for examination. No pains were taken to close this room hermetically, a scupper four inches wide under the lower berth remaining open throughout the experiment.

As the result of these experiments the authors conclude that gas produced under pressure by the Clayton apparatus is sufficient for the disinfection of the holds of ships when they contain objects soiled with the germs of typhoid fever, cholera and the plague.

It will also kill rats, fleas, bugs and other vermin, and will not injure delicate fabrics, grain, sugar, fruit and other objects which form the cargoes of ships.

RECENT ENGLISH EXPERIMENTS.

These experiments were conducted under the direction of the London County Council, and were reported upon by Dr. Murphy, Feb. 10, 1902,¹² the object being to determine the comparative value of different disinfectants used for household disinfection.

The disinfectants submitted to test were carbolic acid, permanganate of soda, bleaching powder, corrosive sublimate, formalin and sulphurous acid.

Seven microbes were experimented upon, including those of typhoid fever, diphtheria, cholera and tuberculosis. Four kinds of material were employed—cloth, unpainted or unvarnished wood, linen and wall paper. Microbes distributed in broth, milk or melted gelatine were liberally applied, and were exposed to the action of the disinfectants.

The typhoid bacillus was killed by all disinfectants except Condry's fluid and bleaching powder.

Condry's fluid gave generally negative results; bleaching powder also failed for the disinfection of cloth and wood infected with the typhoid bacillus after one hour's exposure, but succeeded in twenty-four hours.

The bacillus diphtheriae was killed by formalin and sulphur dioxide. The cholera vibrio was destroyed by all disinfectants except Condry's fluid and bleaching powder.

Anthrax spores were only destroyed with certainty by perchloride of mercury.

For tubercle bacilli, carbolic acid and corrosive sublimate were the only efficient disinfectants.

¹² Report of the Medical Officer of Health, London, 1902.

Neither formalin nor sulphur dioxide were efficient for the disinfection of wood and cloth infected with this bacillus.

DISINFECTION OF NEW CLOTHES.

Sir Charles Cameron¹³ relates several instances in which new clothing appeared to be the vehicle of the scarlet fever contagion. The new recruits of the Royal Irish Constabulary lodged in barracks at Phenix Park, Dublin, were often attacked with scarlet fever, and suspecting the new uniforms as sources of the disease, he ordered them to be disinfected before being used. This measure resulted in a diminution in the attacks.

DISINFECTION OF THE HANDS.

Calvello,¹⁴ after a series of experiments with the essences of essential oils, believes them to be superior to corrosive sublimate for the disinfection of the hands. In consequence of the collection of detritus around and under the finger nails, he finds that the ordinary methods of disinfection are not efficient (scrubbing and the application of soap, alcohol and corrosive sublimate). Some of the essences have decided bactericidal power, and are more penetrating. The essences chosen for experiment were canella, thyme, geranium and patchouly. He at first employed mixtures of distilled water with 6% alcoholic solutions of the fresh essences. He found it necessary to increase their strength to a 9% solution of canella, 12% of thyme and 18% of geranium. These solutions gave satisfactory results. The patchouly has too feeble antiseptic power for general use. The microbes employed for experiment were the staphylococcus pyogenes and the bacillus coli.

SCHOOL BACTERIA.

Under this title Cacace¹⁵ presents the results of some examinations of the dust of schoolrooms in Capua. He found sarcinae, b. coli, staphylococci, blastomycetes, Penicillium glaucum and Aspergillus niger. In one gram of dust collected in the principal class rooms, there were from 5 to 25 million germs; in specimens from the gymnastic hall, 17 to 40 millions, and in the infant school 70 to 193 millions. The month of June appeared to be the most favorable for their development, of the different months of school attendance. Dust collected at the close of each session contained 2 to 5 millions more than at the beginning.

Inoculations of this dust upon guinea pigs caused death by septicemia. Other pathogenic bacteria were found in the blood of the dead animals, but not those of tuberculosis.

The excess of germs in the dust of the infant school was probably due to its location, on the ground floor and near a dusty street.

THE AIR OF UNDERGROUND BAKEHOUSES.¹⁶

Dr. Newman, Medical Officer of Health of Finsbury, England, in an investigation of the bakehouses of his district, presents the following summary:

¹³ Brit. Med. Journ., Feb. 15, 1902, p. 386.

¹⁴ Lavori di Laboratorio dell'Istituto d'Igiene della R. Università di Palermo, vol. v, p. 121.

¹⁵ Centralbl. f. Bakteriologie, Parasitenkunde u. Infektionskrankheiten, vol. xvii, p. 653, 1901.

¹⁶ Public Health, London, December, 1902, p. 159.

The air of the typical underground bakehouses:

(1) Contained 14.8 volumes per 10,000 of carbonic acid (CO_2), as compared with 4.9 in above-ground bakehouses and 4.3 in the streets.

(2) It contained between 10 and 24% less moisture than outside air surrounding the bakehouses.

(3) It contained at least four times more bacteria than surrounding street air, and three times more bacteria than the air of a typical above-ground bakehouse.

BORAX OR BORIC ACID AS FOOD PRESERVATIVES.¹⁷

Vaughan and Veenboer have reviewed the recent literature of borax and boric acid as food preservatives, and present the results of experiments which they had conducted in which chopped meat, butter and cream were treated with definite quantities of borax and boric acid. They conclude that the amount of boric acid to be allowed in chopped meats should be limited to 0.5%, but that there is no objection to the use of as much as 1.5% when it is to be sprinkled on the surface of the meat, since most of this is washed off again. They also give the following conclusions; both from their experiments and from the literature already published:

(1) The use of borax or boric acid as a preservative in butter and cream in the quantities specified in the recommendations of the English commission is justified both by practical results and by scientific experimentation.

(2) The dusting of the surfaces of hams and bacon, which are to be transported long distances, with borax or boric acid, not exceeding 1.5% of the weight of the meat, is effective and not objectionable from a sanitary standpoint.

(3) Meat thus dusted with borax or boric acid does not become slimy, because the preservative thus used prevents the growth of aerobic, peptonizing micro-organisms.

PREVENTION OF FISH POISONING.¹⁸

Prizes of 5,000, 1,500 and 1,000 roubles (\$3,500, \$1,050 and \$700) are offered by the Imperial Academy of Sciences, and the Ministry of Agriculture and Crown Domains of Russia to persons who:

(1) By careful experiments define the qualities of poisons contained in fish.

(2) Investigate the action of the poison on the central nervous system, heart, circulation and digestion.

(3) Present an accurate illustration of the pathological secretions in the various parts of animal and human bodies caused by such poisoning.

(4) Present a description of the signs distinguishing fish containing poison from normal fish.

(5) Indicate methods for the prevention of development of poison in fish; and

(6) Indicate antidotes and general provisions against poisoning by fish.

Essays written in English should be submitted to the Ministry of Agriculture and Crown Domains (St. Petersburg) by Oct. 1, 1903.

MANUFACTURE AND SALE OF ICE CREAM.¹⁹

The corporation of London has published regula-

tions relative to the manufacture and sale of ice cream, the principal points urging the necessity of absolute cleanliness in the places, processes and utensils employed in manufacture. It must not be made in living or in sleeping rooms. If the materials are boiled together, freezing must take place immediately afterward. It must not be kept more than forty-eight hours. If then remaining unsold it must be destroyed.

BRITISH SANITARY LEGISLATION OF 1902.

The past year was not very fruitful in the enactment of new laws relating to the public health. The only new acts of this character were the Cremation Act (2 Edward VII, Chap. 8), the Midwives Act (2 Edward VII, Chap. 17), and the London Water Bill.

By the first of these the burial authorities are permitted to provide and maintain crematories, the plans and site being subject to the approval of the local government's board. No crematory can be established within two hundred yards of a dwelling, except by consent of the owner, nor within fifty yards of a public highway. The Secretary of State must make regulations and prescribe forms of certificates.

By the terms of the Midwives Act, midwives must be certified after April, 1905. After April 1, 1910, "No woman shall habitually and for gain attend women in childbirth otherwise than under the direction of a qualified medical practitioner unless she be certified under this act."

Provision is made for the formation of a central midwives' board, with power to frame rules, appoint examiners, decide on plans and times for examinations, and to issue and cancel certificates of proficiency.

The Metropolitan Water Act did not become a law until Dec. 18, 1902, when it received the royal signature. A water board is thus established for the purpose of acquiring and managing the different water works belonging to the various companies which now supply London. It is estimated that from forty to forty-five million pounds sterling will be needed to carry out this great work. It remains to be seen whether the people of London will still be contented to use the filtered water of the Thames and its tributaries, or will push for more distant and purer sources.

FRENCH SANITARY LEGISLATION OF 1902.

The French government, in February, 1902, adopted a new sanitary code, which went into operation a year later (February, 1903). It consists of five titles and thirty-four articles or sections. The first title, embracing eighteen sections, treats of general sanitary measures, including the prevention of infectious diseases and the sanitation of houses and tenements. The second title treats of the powers and duties of the different sanitary authorities, general and local, including those of the Consulting Committee of Public Health of France.

Title Three treats of the expenses of sanitary work, and Title Four of the penalties for violation of the provisions of the code.

The most important change from former laws is to be found in Article Six:

¹⁷ Am. Med., March 15, 1902, p. 421.

¹⁸ Brit. Food Journ., January, 1903, p. 3.

¹⁹ Brit. Food Journ., December, 1902, p. 267.

"Vaccination is obligatory during the first year of life, and revaccination during the eleventh and twenty-first years.

"Parents or guardians are held personally responsible for the execution of this measure.

"A rule of public administration, adopted after consultation with the Academy of Medicine and the Consulting Committee of Public Health, will fix the necessary measures for carrying out this law."

FRENCH REGULATIONS RELATIVE TO EMBALMING.

Brouardel²⁰ quotes certain French regulations now in force to the effect that a vial containing a specimen of the same substances that have been used in the process of embalming shall be placed by the side of the body.

Reports of Societies.

THE OBSTETRICAL SOCIETY OF PHILADELPHIA.

STATED meeting, Feb. 5, 1903, the President, DR. JOHN M. FISHER, in the chair.

THE ETIOLOGY OF ECLAMPSIA, BY CHARLES S. BARNES, M.D.

The causative factor or factors are not known. The clinical symptoms and pathologic findings are so varied as to lead investigators astray. Several theories of etiology were presented, as the theory of mechanical irritation by the enlarged womb; the so-called pressure theory whereby circulation of the kidneys is thought to be interfered with. Again, the malady has been considered as one of purely reflex origin, through innervation of the splanchnic nerves by pressure or by rhythmic contractions of the womb. Efforts to identify eclamptic convulsions with those of purely uremic origin have failed. The rational conclusion has been reached that the immediate cause of eclampsia is a systemic affection, an auto-intoxication; that the system of the pregnant woman is a laboratory in which are produced substances which may result in a self-destructive explosion. These toxins are probably animal alkaloids. The condition results from the gradual accumulation in the system of nitrogenous waste, due to an excess of nourishment, faulty metabolism and deficient excretory processes, one or all. Davis and Hermann have pointed out that the quantity of urea excreted is the best index of metabolism. The toxemia, however, is not ascribed to urea, but to the excess of urea-forming substances retained in the system. There is at present no good ground for belief in a bacterial source of the disease, though bacterial infection of various sorts predisposes to toxemia. The commonly accepted theory is that toxemia is the result of a vice constructive metabolism.

The question is raised as to the part of the organism responsible. The theory attributing the trouble to a diseased or dead fetus is untenable. Waste from a growing fetus may possibly determine an attack. Recent observers regard the placenta as having a remarkable glandular activity, perhaps liberating toxins into the maternal blood. The kid-

neys, while sometimes a contributing factor, often, instead, suffer the consequences of toxemia. There is strong ground for belief that the liver is the most important of the excretory organs, and that the urea index is significant of the functional activity or inactivity of the liver rather than of the kidneys. In toxemia, the skin is dry and the exhalations from the lungs are especially noxious. Thus the symptoms, though flashed outward by way of the nervous system, point directly to the derangement of the excretory organs. The conclusion has been reached by some that the function of the thyroid, normally enlarged in pregnancy, is to regulate and control metabolism. Numerous contributory or predisposing causes were enumerated, among them heredity, as to disease, temperament or habits; excess of nitrogenous food; inactivity; beverages, alcoholic, tea or coffee; bad hygiene; systemic diseases; diseases of the excretory organs; climatic influence; multiple pregnancy and primiparity; mental depression or undue strain; ptomaine poisoning; exposure; mental or physical shock; pain, especially that of labor.

The immediate cause of a convulsive seizure has been ascribed to an acute anemia of the brain or to edema of that organ. But the most plausible and rational conclusion is that, in toxemia, the poisons circulate throughout the system, including brain and cord, until, the toxins accumulating, there comes a time when the equilibrium of the nervous system can no longer be sustained, and there is an outward discharge of nervous energy in convulsive phenomena. Emphasis was laid upon the predisposing and contributing causes, such as are so imprinted upon the excretory and nervous systems of every toxemic patient that any intelligent and diligent practitioner of medicine may read them, and having read, may employ successful prophylactic treatment of eclampsia.

THE TREATMENT OF ECLAMPSIA, BY WILMER KRUSEN.

Dr. Krusen gives statistics showing the great necessity for further knowledge of this alarming complication of labor. He thinks that to insist dogmatically upon a definite and undeviating method of treatment for this or any pathologic condition is to confess ignorance of therapeutic agencies, since what is exactly adapted to one case may be futile or damaging in another. He divides the treatment of eclampsia into: (1) prophylaxis; (2) treatment of convulsions; (3) treatment during intervals; and (4), after-treatment.

Prophylaxis is directed to the prevention of convulsions and the strengthening of vital processes. The amount of urea excreted is considered the best guide, and when it falls below 1.5% there should be stimulation of all excretory processes. The liver and the intestinal tract should be stimulated by the administration of frequent and small doses of calomel, one-tenth grain three times daily for one or two weeks. Caffeine in three-grain doses, three times daily, may be given for diminution of urine. If there is high arterial tension, nitroglycerin in full doses is indicated. The writer calls attention to the connection between the inadequate action of the thyroid gland and the arrest of renal secretion, quoting Nicholson, who has given thyroid extract in eclampsia with favorable results, and advises that it be

²⁰ Brouardel: *Death and Sudden Death*, 1902, p. 101.

given in five-grain doses night and morning, and proteid foods avoided. Saline solution dilutes the poison in the blood and produces diuresis and diaphoresis. Iodid of potassium is sometimes added to the saline solution, the iodine acting as a stimulant to the thyroid gland. Dr. Krusen thinks that upon a thorough investigation of the relationship between the thyroid gland and pregnancy depends much of the future success in the prophylaxis of eclampsia.

In the treatment of the convulsions he considers chloroform as the anesthetic *par excellence* for their control, and inhalation of it should be continued until the paroxysm abates. Oxygen may be given in conjunction with it. Ice bags applied to the back of the head and neck will also aid in warding off and controlling the attacks.

In the treatment during the intervals one of the most important measures is venesection. It is indicative when the pulse shows high arterial tension, is full, rapid and bounding, and the face of the patient is suffused or almost cyanotic. In such cases it frequently rescues the patient from impending pulmonary edema and apoplexy; and it also abstracts a large amount of noxious principles from the system and will do more for the relief of the patient than any other one procedure. By using copious injections of normal salt solution the depressing effect of bleeding can be counteracted and the unknown toxins diluted. Since the salt solution stimulates the heart, promotes diuresis and diaphoresis and dilutes the toxin, it must be classed as a rational method of treatment. Bicarbonate of potassium is sometimes added to the solution. Morphia can be used hypodermatically. It is an agent of great power and rapid action, things often essential in the prevention of repeated convulsions. The writer condemns hot air and hot-water baths, and advises as purgatives croton oil, calomel or some saline; as carbon dioxide poisoning soon occurs in cases of repeated convulsions, oxygen by inhalation may be used. In regard to obstetric treatment, he believes that the teaching of Duhresen is sound, that if eclampsia comes on during the last month of pregnancy when the child is viable, its speedy extraction is desirable. But the high mortality of Cesarean section leads him to condemn that operation unless some condition, such as pelvic deformity, prevents vaginal delivery. If the patient is in the second stage of labor, all authorities agree that the uterus should be emptied as speedily as possible, but in cases in which labor has not begun, or is in the first stage, opinions differ. But as expectant or palliative treatment means certain loss of the child and the loss of 30% of the mothers, he believes that while the obstetrician should not cease to combat the convulsions, the sooner he produce or hastens labor the better for both lives concerned. Mechanical dilation of the cervix, either manually or with dilating bags, or deep cervical incisions, properly performed under rigid antisepsis, is the best method of procedure. Delivery should be accomplished as rapidly as possible, since the prompt emptying of the uterus contributes greatly to the recovery of the patient. The after-treatment should be carried out along the ordinary lines followed in the care of the puerperal patient, but with more absolute quietude, and with more vigilant attention to all the excretory organs.

DR. R. C. NORRIS. The papers that have been

presented have outlined our knowledge of the etiology, the pathology and the treatment of eclampsia about as accurately as could be done. There are a few points which I think this discussion should emphasize.

In regard to etiology, the profession, recognizing the fact that eclampsia is believed to be a toxemia, should pay attention to the functional activity of the liver of the pregnant woman quite as closely as to that of her kidneys. It is common practice to have a bottle of urine of the pregnant woman sent to the physician and to have it tested for albumin and for its specific gravity, and so long as albumin is not found and the specific gravity is near the normal, no further attention is paid to the case. I believe that such an examination of the urine is absolutely worthless, except when grave kidney lesions exist. Others will go farther and have a critical analysis of the urine made, involving a knowledge of the amount excreted in twenty-four hours and the percentage of the urea, and so long as they find these two factors approaching the normal they will give no further attention to the case. This I also believe is a false security. While we know that 2% of urea is the average amount passed, we must know that this 2% represents a proper quantity of urine passed. Moreover, it is our duty to know not only the amount of excrementitious products the patient is able to excrete, but we also must have knowledge of what may remain to create a toxemia. That is only learned by seeing the patient frequently and noting the general symptoms of toxemia, such as headache, neuralgia, coated tongue, hebetude, salivation, insomnia, nervous irritability, eye symptoms, etc. The approach of a toxemic storm usually can be seen by the alert physician. In a case under my care in which the most critical urinalyses were made with normal findings, the constitutional condition presented symptoms of toxemia requiring the most vigorous treatment. While urinalysis is most important, it should be remembered that it is only an index of kidney elimination and fails to indicate the metabolic and toxin-destroying power of the liver.

When we come to the question of treating these cases, I agree with the author that prophylactic treatment is the most important. Drugs that aim directly to promote the activity of the liver are more valuable to the pregnant woman than diuretics. Diet that lessens the tax on the liver is most important. Calomel with salines should be used frequently by a pregnant patient, apparently perfectly well, for she needs to have her liver prodded whether constitutional symptoms indicate that things are going wrong or not. A point of practical value is lavage of the intestines. While we do not know to what extent the intestines are involved in the etiology, I do know that toxemic patients in my practice receiving intestinal lavage two or three times a week show improvement.

When we come to the treatment of convulsions, there is a wide variation in the discussion of details. Dr. Krusen omitted mention of chloral and of veratrum viride, and laid special stress upon bleeding. He is, no doubt, correct that bleeding is indicated in some of the cases, but in some cases the women are anemic; there is pallor and the blood count will show diminution in the proportion of hemoglobin

and in red blood corpuscles. Depriving such patients of 20 to 30 oz. of blood does distinct harm. Such cases are better treated by the use of *veratrum viride*. The anemia of pregnancy is closely associated with toxemia, and has a practical bearing upon the use of venesection. When the pulse is 160 to 180 with but little volume, and when the patient shows profound anemia, an abstraction of 20 to 30 oz. of blood may be distinctly disadvantageous and is not going to eliminate much poison. It will lessen blood pressure, and the real value of bleeding for eclampsia is the action upon the blood pressure. The modern practice of not bleeding every case is better than bleeding every case. We must use the best of judgment when deciding in favor of venesection, bearing in mind the condition of the pulse and the blood count. There is a wide diversity of opinion as to the value of *veratrum viride*. I cannot understand why some men do not appreciate its value, unless it be that they have never employed it. I have repeatedly used it and, so far as the cessation of convulsions is concerned, have observed more benefit than from any other drug I have ever employed. It, too, must be given cautiously. The dosage differs according to whether the tincture or fluid extract is employed. I have seen a patient nearly killed by the use of twenty drops of the fluid extract administered hypodermatically. The initial dose should be five to eight drops of the fluid extract, to be repeated as soon as the effect diminishes. Sufficient should be used to keep the pulse in the neighborhood of 70 or 80. I am sorry Dr. Krusen did not discuss that in his paper. The value of full doses of chloral is well known.

I would like to give a word of warning as to the use of salt solution. I have found in some cases that an excessive amount of salt solution has aggravated the condition of the kidneys, has produced edema of the lungs, and helped to do the very thing which we aim to avoid. I should place as a limit one quart of salt solution and no more, until free diaphoresis, diuresis or catharsis has occurred. When there is edema of the lungs, it should not be employed at all. I have seen edema of the lungs aggravated and the patient's serum run out of her mouth as the result of too free use of salt solution. Large amounts of salt solution are of greatest value when *profuse* catharsis from saline purges has occurred.

I do feel that morphia is always contraindicated, but would reserve it for aggravated cases in which the convulsions recurred with great frequency and were not otherwise to be controlled. One grain to a grain and a half until the convulsions have ceased is an average amount to be employed.

Chloroform to be of any value must be administered by some one who can recognize the onset of a convulsion. There are prodromal symptoms of the eclamptic seizure, and during these is the time for the administration of the chloroform. Upon an attempt to give it during a seizure it will be found that very little enters the lungs, and for the same reason oxygen cannot be taken except between the convulsion seizures.

The necessity for delivering eclamptic patients quickly is always discussed. I have believed, on theoretical grounds, and practically my experience has borne it out, that the speediest method of de-

livery is not the safest one. If that were true, Caesarean section would be the ideal method. Next to that is rapid dilatation or incision of the cervix. I have incised the cervix and done craniotomy upon a dead baby, delivering the baby in eight minutes. This winter at Blockley I had an eclamptic patient on whom I did a Caesarean section. Both patients died in coma, despite most rapid deliveries. The method of the rubber bag to dilate the cervix in these cases of primigravidae with rapid cervixes is often too slow. The first duty is to treat the case medically, eliminate poisons, control the seizures, and then to begin by slower, less aggressive means to secure dilatation of the cervix. Here again we must consider the individual case. Some women are so weak that the shock of anesthetic and dilatation of the cervix will carry them beyond the point of recovery. Experience and good judgment are required for selecting a method of dilatation where the cervix is rigid. When the convulsions have been controlled, and when the patient has passed out of her coma, the rubber bag is sufficient. When the patient remains comatose, with repeatedly recurring convulsions, she should be kept under an anesthetic and a metal dilator used, such as Bossi's four-branched instrument, and the child extracted with forceps. That rapid method should be resorted to for desperate cases only. In other cases which improve under medical treatment, the slower plan of dilatation is safer.

To recapitulate, the practical points that I would emphasize are that while urinalysis is important, it must go hand in hand with personal interviews with the patient, to note the first signs of approaching toxemia; that the use of prophylactic measures includes, as most important of all, diet and attention to the woman's liver, and that among the means of elimination of toxins during pregnancy, the use of the intestinal canal is most valuable. For the control of convulsions, I would speak in praiseworthy terms of *veratrum viride*, and for rapid elimination of toxins, I would also speak of the value of free saline purgation. In an experience of ten years that has given me eight to ten eclamptic patients in consultation each winter and one or two additional in my own hospital, with but one exception, I have yet to see a patient die who responded to the free use of saline purges, in conjunction, of course, with other treatment. Speedy delivery is not always to be desired. Only in the gravest cases is this advisable, and then instrumental dilatation of the cervix offers the safest and best means of delivery.

DR. STRICKER COLES: I would refer especially to the early symptoms and to the prevention of eclampsia. I may have to change my ideas about this condition, but I believe from the cases I have seen that this disease is a preventable one. In other words, I believe that 90% of eclampsia can be prevented.

In my experience I have seen clinically three forms. One begins with Bright's disease. Some women may go into Bright's disease without any apparent toxemia. Of these cases I have had some eight or ten without any death at all. I look upon these as cases without danger, although some have albumin and almost solid urine. With reference to the mother there is very little danger, but this is not

the fact with reference to the child. Of these babies I have lost some before and some after birth. It is not easy to raise these children. The next form is that from toxemia. The patient has the symptoms of toxemia, headache, restlessness, malaise, indigestion and all the symptoms of toxemia, and the urine of these cases some two or three weeks before the patient will go into convulsions will show some signs. This sign will be in the amount of urea. If we find a patient eliminating 1.5% of urea with a normal amount of urine we do not find symptoms of toxemia. The danger point in my experience is when it reaches 0.5 of 1% I have never yet examined such cases in which the patient did not have headache and all the symptoms of toxemia. I have never seen a patient with a form of eclampsia that could not have been prevented.

(To be continued.)

Recent Literature.

Regional Minor Surgery. By GEORGE GRAY VAN SCHAICK, M.D., Attending Surgeon to the French Hospital, New York. Published by the International Journal of Surgery Co., New York. 1902.

The author in writing this book has striven to avoid subjects of a technical character as far as possible. He desires to describe the surgical treatment of these lesions daily encountered by the general practitioner, and the methods presented represent conclusions based on a personal experience of eighteen years of hospital, dispensary and private practice. The writer very justly claims that "minor" surgery well done often renders "major" surgery unnecessary. Hence the importance of this subject to the general practitioner.

The book is a small volume of 226 pages. It is well written; it is also confined closely to its proposed scope, an unusual feature in this type of book. The directions given are brief, definite and unobscured by theorizing. It is essentially a practical manual, and although in some instances there might arise a difference of opinion as to the method proposed being the most efficient, still it is usually a good one. Diagnosis of the commoner affections is briefly treated. After-treatment, as a rule, is omitted. The general way in which solutions and drugs are usually mentioned presupposes a considerable knowledge of surgical materia medica. With the exception that it is defective in its description of details of procedures, the book is attractive. It contains many practical suggestions, and its arrangement is good.

The Treatment of Fractures. By CHARLES LOCKE SCUDDER, M.D., Assistant in Clinical and Operative Surgery, Harvard Medical School, etc. Third edition, thoroughly revised. Philadelphia and London: W. B. Saunders & Co. 1902.

This work, the first edition of which was published in 1900, has not been allowed by its author to "gather moss." It is unusual for a book of this character to reach its third edition in so short a time.

It now appears as an octavo volume of 485 pages, increased from 457, with 645 illustrations in place of 611. Several new but not uncommon fractures are described. The chapter on gunshot fractures of the long bones is derived from a review of the observations acquired by the recent experience of military surgery with the effects of small caliber bullets.

The general text of the book has, the author states, been carefully reviewed, and an index appended. Photographs have been substituted for drawings in many instances, and the use of plaster-of-Paris more extensively illustrated. The general character of the book is preserved. It serves as a guide or manual for the treatment of fractures. The methods are, as a rule, described in detail. The author aims to not only tell *what* to do, but also *how* to do it. He tries to show by descriptive text, diagrams and illustrations of actual cases, the exact conditions which exist. The radiograph has been extensively employed for this purpose. The book is a valuable treatise on this especial branch of surgery, and represents well the present status of practice. Also the work of the publisher sustains the high standard of excellence shown in the former editions.

The Mattison Method in Morphinism. A Modern and Humane Treatment of the Morphine Disease. By J. B. MATTISON, M.D. 12mo., pp. 40. New York: E. B. Treat & Co. 1902.

This little book is a detailed description of a method of treatment of the morphine habit which the writer claims has proved successful in many cases, and is not attended with the suffering so common in many attempts to break off the habit. The essential features of this method are a moderately rapid withdrawal of the morphine, in about ten days on the average, and the production of a certain degree of nervous sedation and a consequent control of reflex irritation by bromide of sodium. Beside the details of this method of treatment, full directions are given for the treatment of such other conditions as may arise during the progress of the work.

The Proceedings of the Charaka Club. Volume I. New York: William Wood & Co. 1902.

There was organized in 1898, in New York City, a club of about ten medical gentlemen, who were interested in the history of medicine and in its artistic and literary side. The name of the club was taken from the Hindoo sage, whose work is the oldest on the subject of Hindoo medicine. Some of the communications of the members are contained in the present volume, a handsomely printed book of nearly one hundred pages, with an elaborate book-plate, and a number of half-tones and woodcuts. It has been edited for the club by Dr. Charles L. Dana, and the edition is limited to three hundred copies. The articles on "Hindoo Medicine," on the "Statues of Æsculapius," with its handsome illustrations, and on "The Evil Spoken of Physicians" deserve especial notice.

THE BOSTON

Medical and Surgical Journal

THURSDAY, MARCH 19, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

283 WASHINGTON STREET, BOSTON, MASS.

ECLAMPSIA.

RENEWED interest in the study of eclampsia has followed the general advance in medical investigations in the last few years, and considerable attention has lately been given to the subject in recent medical literature. As long as our understanding of the etiology is at fault, so long must our treatment be empirical and consequently never uniformly successful. Good work has been done in various quarters in the endeavor to discover the correct etiology. Treatment has advanced prophylactically in that we can recognize pre-eclamptic symptoms and can often prevent convulsions by various timely measures. The problem of the true cause of the symptoms, however, still remains unsolved, but the close study which eclampsia is receiving, with the trend given to it by our advancing knowledge of physiology and pathology, will doubtless end before many years in its correct solution.

An extended discussion of the whole subject appeared in the February *Practitioner*, but a brief review of the theories of the etiology and treatment is of interest here. It is now generally conceded that eclampsia is not a disease of the kidneys, but arises from the circulation in the blood stream of one or more poisons of which the exact nature is unknown. These poisons appear to gain access to the circulation either from the alimentary canal or from the body metabolism or from both. The pregnant woman, having to deal not only with the results of her own tissue changes, but also with those which occur in the fetus, is more liable than under other circumstances to auto-intoxications. The organs of defence—the liver, kidneys, thyroid, etc.—are normally capable of dealing with these products, but when in the pregnant woman a breakdown in any one of these organs occurs, the whole mechanism is upset and a toxemic condition results. The toxic

material, passing through the kidneys, begins to irritate and injure them, the renal function fails and albuminuria appears. The failure of the kidneys to excrete the toxins leads to their accumulation in the body, and unless the normal condition is re-established serious consequences follow. In most women the defensive organs remain adequate throughout pregnancy. In many, some slight early disturbance is overcome as the organism readjusts itself to reproductive life. In others, however, the vicious circle once established continues until eclampsia or some other serious condition is the result; or the injury done the kidneys in a first pregnancy is increased in each subsequent one, until they become permanently damaged, and chronic Bright's disease is established.

Though the theory above outlined is perhaps the one most widely accepted as a working hypothesis, since it seems to fit most closely the clinical facts to be explained, there are as yet no clear proofs of its correctness.

Various investigators have attempted to prove for eclampsia a bacterial origin. The micro-organisms are supposed to exist in the uterine cavity and eclampsia to be preceded by the absorption of their toxin. Since the condition may arise after labor, the uterine wall, and not the fetus and placenta, is regarded as the site of bacterial growth. An attempt has been made to draw a parallel between septicemia and eclampsia, both being general intoxications, and the convulsions in the latter being due to the sudden absorption of large doses of poison, while the former is due to its slow continuous absorption. A recent writer also endeavors to compare these conditions to many abortions and premature labors, especially those which run a septic course, in which micro-organisms are latent in the decidua and renew their activity during pregnancy. It is noted that the uterine cavity is well drained except during the pregnant state. But so little material is available for bacterial examination in eclamptic patients that no single organism has been indicated as the causative agent, and the theory must long remain unproved.

A third and very interesting theory is that which ascribes eclampsia to thyroid inadequacy. The thyroid is enlarged during normal pregnancy, and a larger supply of iodothyrim is needed in the pregnant than in the non-pregnant state. It is supposed that a deficiency of this secretion causes the metabolism of nitrogenous substances to stop short of the formation of urea and at a point where the products are highly toxic. The clinical features of a typical eclampsia resemble those of complete athyroidia, as caused by the complete removal of the thyroid in animals. And eclampsia is thus regarded as a

temporary athyroidia. A woman in the pre-eclamptic state is put to bed and fed on milk. Her demands for thyroid secretion are lessened, and nitrogenous metabolism becomes complete again. Meat diet or, on the other hand, increased physical exertion, would again disturb the balance. Eclampsia may also follow a meal of meat or excessive muscular effort, such as labor.

The relation of the kidneys to the thyroid may be that iodothylin is a diuretic, or that urea is the real diuretic, but depends for its formation on iodothylin, or that the latter is a powerful vasodilator and maintains the renal circulation, in antagonism to the suprarenal secretion. Bearing on this theory may be mentioned the experiment with a cat, whose thyroid was removed and who became pregnant three years later. When labor set in she became comatose and had convulsions. Five days later, with the intramuscular injection of thyroid extract, the convulsions ceased, labor advanced, and the following day a dead kitten was born. The cat recovered completely.

Lastly, the mechanical theory of the causation of eclampsia has been reiterated recently by Herzfeld, who, after making a large number of autopsies on eclamptics, ascribed it to the gradual compression of the ureters by the growing uterus, and considered Cæsarean section as the indicated treatment for anuria occurring in a parturient woman with presumably dilated ureters.

Based on the toxemic theory, the treatment of pre-eclamptic symptoms, which may be easily diagnosed long before convulsions occur, is obviously of great importance. The well-known danger signals—vomiting, headache, nervous irritability and disturbances of vision, accompanied by decreased urine and urea, albuminuria and edema—are usually successfully met by rest in bed, milk diet, purgation, etc. An interesting addition to these commonly employed measures, suggested by Nicholson's thyroid theory, is the administration of thyroid extract, of which the value appears to be proved by his reported cases.

As to the advisability of obstetrical interference in the presence of convulsions opinions differ. But when dilatation of the cervix is already advanced, it seems agreed that labor should be completed artificially as quickly as may be done with gentleness. Hemorrhage is not to be checked. For the treatment of the convulsions preceding labor, the ground is more debatable. Some authorities cling to *accouchment forcé*, while others regard the shock of the operation too severe for a woman already so toxemic. They consider such treatment, if applicable to mild cases, at least improper for severe ones, since emptying the uterus cannot re-

move quickly a poison which has been accumulating for months. Cæsarean section has been recommended and used instead of *accouchment forcé*, but the question of the advisability of ending pregnancy abruptly by any procedure at all must be decided before any single method can be preferred to some other.

Bleeding and the injection of salt solution seem to have an established position in our present treatment; and again, for the convulsions, it is interesting to note the recommendation, based on theory and in certain cases borne out by its practical success, to give large doses of thyroid extract, with the view, not of affecting metabolism, but of reducing blood pressure, of relaxing the renal arteries and re-establishing diuresis. *Veratrum viride* is widely employed, especially in this country, but its use has some strong opponents.

THE EPIDEMIC AT ITHACA.

MR. JAMES C. BAYLES, the well-known sanitary engineer, who was formerly president of the New York Health Department, has been making an investigation of the typhoid epidemic at Ithaca, and writes from there under the date of March 10 that the best data obtainable in regard to it are admittedly incomplete. They show, he says, that up to the end of the week previous there had been 755 cases of the disease in Ithaca since Jan. 10 of which the clinical history is obtainable. The number of unreported cases is a matter of estimate. In view of the fact that most physicians have neglected and that some have refused to make returns, and that in death certificates some of them persistently refrained from assigning causes likely to be recognized as typhoid complications, he expresses the opinion that the number of cases, light and grave, occurring since the epidemic began would be conservatively estimated at 1,000. It is impossible to learn the number of deaths or to calculate the percentage. The returns to the board of health have not been tabulated, and he has tried in vain to get the figures. "I do not know," he goes on to say, "how many cases there are at present in Ithaca, but I am constrained to estimate that there are not less than 250 cases of which no official record has been made. If told, as I have been, on very good authority, that the number was double this estimate, I should not find myself disposed to dispute it. A great many of these cases are of a kind popularly known as walking typhoid. . . . What potentialities of mischief in disseminating the infection reside in these neglected ambulant cases may be learned from the books."

Just a year ago conditions existed in Ithaca which

should have startled the community into instant and energetic measures of self-protection. There was then a local epidemic of a disease closely resembling a mild type of typhoid. Its statistics are incomplete and unsatisfactory, but it was very prevalent, and more than one hundred cases were treated. More than this, typhoid has been more or less prevalent for many years, and at no time has the town long been free from it. For at least ten years the cautionary signals have been obvious to any one who might have chosen to look for them. After a careful investigation, Mr. Bayles has failed to find any evidence in support of the theory which obtained credence in Ithaca and was accepted by the State Board of Health, that the water of one of the creeks supplying the town became polluted from a case or cases of typhoid among a colony of foreign laborers who were constructing a dam. That there are no cases of typhoid on the watershed or along tributary streams, he is not prepared to say or to believe. That the water company was negligent in the matter of the policing of its watershed and minimizing causes of possible pollution is not open to discussion—that it was exceptionally so does not appear. If other causes of danger were corrected, there need be no reckless precipitancy in dealing with the problem of the local water supply. However bad it may be, now or normally, it is the least of the dangers to which the people of Ithaca are exposed. During the coming summer work will be done which will insure the distribution of a water supply of attested and indisputable purity and potability. "But," he remarks, "those who believe that this will solve the problem of the sanitation of Ithaca are credulous indeed."

One in a position to observe without prejudice the conditions existing in the more densely populated neighborhoods of the town has good reason to feel in the highest degree apprehensive of what may be expected when warm days are here and especially when the flies become industrious. On the basis of such a sanitary administration as Ithaca has become habituated to and has deemed sufficient, it might very well be four or five years before typhoid fever ceased to be epidemic in Ithaca. This would be practically without reference to the quality of the water supply. Fortunately the direction of affairs has been assumed by Dr. George A. Soper, a competent, experienced and energetic man, who has been selected for this service by the State Board of Health. He has planned a sanitary campaign which the common council has ratified by giving the board of health *carte blanche* and a practically unlimited credit. The test will come when it is necessary to point out to well-to-do citizens the nuisances for which they are primarily,

and it may be solely, responsible, to interfere with vested wrongs sanctioned by immemorial usage, and to apply pressure to those reluctant to do on their own premises what they recognize should be required of their neighbors. Dr. Soper can, and, if properly seconded, will, make Ithaca clean and wholesome, and do it in the least possible time. Under date of March 13, Mr. Bayles states that the wisdom of the choice of Dr. Soper is to be seen in the remarkable work which he has already accomplished, and in the basis of confidence afforded that it will be quickly and completely successful. Four more deaths from typhoid among Cornell students, who had returned to their homes, have been reported in the last week.

LEAD POISONING AND PUBLIC WATER SUPPLIES.

BEFORE the general introduction of public water supplies in cities and towns, cases of lead poisoning were occasionally reported which were undoubtedly due to the action of certain well waters upon lead, where conditions existed which were favorable to such action.

One of the earliest American reports upon this subject is a report of a special committee appointed in 1842 by the city of Lowell, in which the committee noted with special emphasis "the readiness with which the Lowell ground waters dissolve lead in dangerous quantities, and warned the inhabitants of the city against the use of lead pipes for the conveyance of drinking waters."¹

Since the introduction of public water supplies, such cases have not been of common occurrence in towns supplied with surface waters, but among the inhabitants of certain cities and towns using ground-water supplies there has been an unusual number of reported cases, where conditions in the soil existed which were favorable to the action of the water upon lead. In some instances, as at Lowell, the introducing of a new supply was followed by an outbreak of lead poisoning. Here the drinking of unfiltered water of the Merrimac River was shown to have given rise to epidemics of typhoid fever, but this water had not been known to act unfavorably upon lead. A change having been made, and the water of driven wells substituted for the river water, the ground water of some of these wells was found to dissolve lead in dangerous quantities. Fifty cases were reported to the State Board of Health by the physicians of that city.² As many more were also reported at Kingston, Milford and Hopedale, Fairhaven and Milton, all among users of ground water

¹ Report of State Board of Health for 1898, p. xxxvii.

² See Thirty-first Annual Report of State Board of Health (1899), p. xxxiv, 30.

supplies, and in many instances where comparatively new lead pipes were in use.

Studies of this important question show that the clear and practically colorless ground-water supplies, which most actively attack lead, are those containing the most carbonic acid and a small or medium amount of mineral matter.

In one or two instances a highly colored surface water was found to attack lead, if allowed to stand in the pipes for a considerable time, the lead being found both in solution and in suspension; since a coating of organic and mineral matter forms upon the pipes, carbonic acid is generated, which, together with the oxygen present, attacks the lead, and this deposit is, when the water is drawn quickly after hours of rest, apparently easily detached from the pipe and drawn out. Thus the amount of lead in water drawn after periods of rest is increased above that which is actually taken into solution by the water during this period of rest. This action of a highly colored water agrees with the recent investigations of the British government upon some of the peaty waters of England.

These facts show that the use of lead pipes for the conveyance of drinking water is attended with danger. If used at all, the standing water in the pipes should be allowed to run till all the water in the lead pipe has been drawn off, before taking water for drinking or cooking.

For several years the local government board of England has been engaged in making investigations upon the character of the moorland waters of Lancashire and Yorkshire. These waters are collected from watersheds in which there are large areas of peaty soil, and in some instances, as at Sheffield, have given rise to epidemics of lead poisoning. Twenty-three water supplies were investigated, the objects of the inquiry having been as follows: To determine, —

(a) What are the seasonal modifications of each of such contributory waters;

(b) In what way and to what degree they differ at one and another time from each other as regards their constituents;

(c) How far diversity of their ability to dissolve lead is associated with seasons of the year, and is at the same time parallel to observed differences in their chemical and bacterial characters.

A careful survey was made of all the gathering grounds of the different water works in question, in order to ascertain the physical characters of the different drainage areas and the chemical quality of the various waters as regards their action, with respect to acidity, and their action on lead.

The results of this important investigation have just been published in a report made to the Local

Government Board by Dr. Houston.¹ The following portions of a condensed summary present the several conclusions embodied in the report: —

1. The history of epidemics of lead poisoning due to water supply, at all events in the north of England, clearly shows that the towns which have suffered in the past derived their water supply from moorland sources. In some cases we know that the water was acid, and in others there was every reason to infer that the water was in a similar condition, since the physical circumstances of the gathering ground were the same.

2. Moorland gathering grounds are usually rich in peat. The amount of peat varies greatly on different gathering grounds, both superficially and in depth.

3. Moist peat has been found to be invariably acid in reaction.

4. The water draining from peat is always acid. The amount of acidity depends chiefly on the amount of peat and the length of time the water has been in contact with it.

5. Acid peaty water dissolves lead.

6. The degree of plumbo-solvency of a water is chiefly governed by the amount of its acidity.

7. Moorland spring water is neutral, and often possessed of slight acid-neutralizing ability. In virtue of this property spring water is commonly capable of neutralizing a certain proportion of acid peaty water.

22. While the cause of plumbo-solvency is to be traced to the presence of acid in water, and the source of the acid to contact with peat, the antecedent cause of the acidity of moorland waters seems to be associated, at all events in part, with the presence of acid-producing bacteria in the peat itself.

23. Certain microbes isolated from peat possess the power of rendering by their growth a sterile neutral decoction made solely from peat both acid and possessed of plumbo-solvency.

24. Acid peaty waters have the power of dissolving not only bright lead but old coated lead, and the action is a very rapid one.

25. Neutral waters do not dissolve lead to any appreciable extent, but they sometimes act on *bright* lead by eating away the surface of the metal in the presence of dissolved oxygen ("erosion").

26. The power of "eroding" lead is an inherent property of water containing oxygen. All waters do not "erode" lead, because most of them contain substances which coat the bright surface of the metal and so prevent any further action taking place.

27. Some moorland waters are not only acid and possessed of plumbo-solvent ability, but "erode" lead as well. But in the absence of associated acidity and plumbo-solvency, ability to erode lead appears to be of secondary importance. Erosive ability *per se* is not to be regarded as an intrinsically dangerous quality of a water unless under special conditions and in the presence of bright lead.

28. Risk of a water acquiring plumbo-solvent ability may be guarded against by methods designed to exclude from the supply contributory waters which experience

¹ Papers on Lead Poisoning and Water Supplies, submitted by the medical officer of the Local Government Board.

Presented to both houses of Parliament by command of his Majesty. London, 1903.

has shown to be conspicuously and uniformly acid, and also by mechanical contrivances to prevent access to the supply of the "first-washings" of peaty soil after periods of drought.

29. Plumbo-solvent ability which has been acquired by water about to be sent to consumption may be removed by suitable arrangements for neutralization. It is of advantage to combine such arrangements for neutralization with sand filtration.

30. I would urge, as a practical outcome of this inquiry, that the circumstances of every supply of moorland origin should be considered with reference to the factors of plumbo-solvency which exist upon it; and in this report I have endeavored to make clear the nature of these factors and their relative importance. It is advisable in the case of existing works to test, not only in the reservoirs and main streams, but also in the tributary streams and subsidiary "feeders" during different seasons of the year, and under ordinary and extraordinary conditions of the rainfall, in order to arrive at a satisfactory conclusion as to the liability of the supply in general, and of its constituent waters, to acquire plumbo-solvent ability. Study of this sort affords the most satisfactory means of determining how best to apply the remedy, or combination of remedies, needed in the particular instance. In the case of proposed new water works, this inquiry indicates the necessity of a careful survey of the physical characters of the gathering grounds, as well as of ascertaining the proportion of spring water to surface water at different times of the year and under different conditions of rainfall, and of testing the quality of the spring water and its power of neutralizing acid, and the quality of the surface water, especially during wet weather and sudden storms following a period of drought.

MEDICAL NOTES.

PROFESSOR KOCH A MEMBER OF THE FRENCH ACADEMY OF SCIENCES. — According to the *British Medical Journal*, Professor Koch has been elected a Foreign Associate Member of the French Academy of Sciences in place of the late Professor Virchow.

SOCIETY OF TROPICAL MEDICINE. — A society for instruction in tropical medicine has been formed in Philadelphia, the object of which is to instruct physicians in the special diseases likely to be encountered in tropical countries. Many of the leading physicians of the city are interested in the movement.

A MEDICAL JOURNAL FOR SOUTH AFRICA. — It is reported that a medical journal with the title "South African Medical Record" is to be published at Cape-town, as a monthly.

PLAGUE. — The *Lancet* is authority for the statement that during the week ending Feb. 15 neither cases of, nor deaths from, plague occurred in Egypt. The last case occurred at Tant-el-Ghezireh on Feb. 6. As regards the Cape Colony, the medical officer of health of the colony stated that for the week ending Jan. 31 two cases of plague were discovered

at Port Elizabeth; namely, a native male who was admitted to the observation ward on Jan. 27, and who died from plague on the 29th, and a colored male who was admitted to the plague hospital on Jan. 31, and who died on the same date. One case remained under treatment at the plague hospital, Port Elizabeth, at the end of the week. No case of plague has occurred at any other place in the colony.

SMALLPOX IN SCOTLAND. — During the first two weeks in February only two cases of smallpox were reported in Scotland, and one of those was a sailor arriving from another port.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, March 18, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 18, scarlatina 28, typhoid fever 18, measles 34, smallpox 2.

BOSTON MORTALITY STATISTICS. — The total number of deaths for the week in Boston was 257 as against 255 the corresponding week last year, showing an increase of 2 deaths, and making the death-rate for the week 22.86. The number of cases and deaths from infectious diseases was as follows: Diphtheria, 17 cases, 6 deaths; scarlatina, 34 cases, 1 death; typhoid fever, 5 cases, 2 deaths; measles, 18 cases, no deaths; tuberculosis, 34 cases, 30 deaths; smallpox, 1 case, no death. The deaths from pneumonia were 40, whooping cough 5, heart disease 29, bronchitis 9, marasmus 3. There were 8 deaths from violent causes. The number of children who died under one year was 46, under five years 68, persons over sixty years 68, deaths in public institutions 84.

A NEW ANTIVIVISECTION BILL. — Hearings have this week been held before a legislative committee at the State House in relation to the restriction of vivisection in Massachusetts. The hearings have been much less prolonged than heretofore.

NEW YORK.

DEATH OF COL. M. C. MURPHY. — Col. M. C. Murphy, president of the New York Board of Health from 1898 to 1901, died on March 5. His case was one of great medical and surgical interest. In 1890 gastrotomy was performed on him by Dr. R. F. Weir, on account of stricture of the esophagus, and ever since then alimentation had been maintained through a tube passed into the stomach through the abdominal wall. Colonel Murphy commanded the One Hundred and Seventieth New York Volunteers in the civil war.

THE VALUE OF A SKULL. — Through his complaints to the police of the teasing of his friends, it recently became known that a South Carolina negro, James Mandy, now living in the city, had made a contract for the sale of his skull to a member of the medical profession, who is much interested in craniology. The latter learned of the extraordinary thickness and hardness of this skull through the man's giving exhibitions of its quality in a dime museum. According to the terms of the agreement the physician is to pay Mandy \$500, in monthly installments of \$5. If Mandy dies before the entire sum is paid the skull goes to the physician for the amount paid up to that time, and if the physician dies before Mandy, it is to go, at the latter's death, to the Medical Society of the County of New York.

A CURE FOR MALARIA. — According to *The Journal of Tropical Medicine*, Dr. Dempwolff, who succeeded Professor Koch as head of the German expedition for the prevention of malaria in German New Guinea, states that he has discovered an aquatic insect which destroys the *Anopheles* mosquito. He proposes to cultivate these insects artificially, and by this means to exterminate the malaria mosquito.

A CENTENARIAN. — James Colston, a centenarian, died in Brooklyn, on March 3. He was born in London, England, in March, 1803.

A SPIRITUALISTIC ARGUMENT AGAINST LIQUOR. — One of the most novel and startling arguments against the habitual indulgence in alcoholic beverages that was probably ever adduced was that set forth in a recent address in Brooklyn before the New York State Spiritualists' Association. "If the men of to-day," said the speaker, "knew how many spirits (of departed toppers) hang around the corner saloons suffering tortures because they can't get a drink, they would be more careful in fostering the dangerous drink habit." How much practical deterrent effect the promulgation of this truly harrowing thought may have remains to be seen.

TYPHOID FEVER AT WEST SENECA. — Health Commissioner Lewis announced on March 11 that Dr. W. D. Green, health commissioner of Buffalo, and Dr. Edward Clark, his deputy, had consented to serve as representatives of the State Department of Health to co-operate with the local health officer for the suppression of an outbreak of typhoid fever which has occurred at West Seneca, and to take proper precautions for the protection of the water supply of Buffalo. There were some 170 known cases, which were stated to be confined to the foreign element among the employees of the Lackawanna Steel Company.

Miscellany.

THE ILL HEALTH OF HERBERT SPENCER.

DR. GEORGE M. GOULD, in *American Medicine* for March 7, 1903, contributes an article on "The Ill Health of Herbert Spencer." As in his "Biographical Clinics," he traces for this other distinguished man of letters the relationship between his ill health and ocular defects. For the biographical basis of his paper, he quotes from the article by Iles in the *World's Work*. Spencer was less of a sufferer than Carlyle, De Quincey and the others, owing to the systematic regulation of his habits of life and methods of work. He employed an amanuensis, and very largely dictated his writings, and frequently interrupted his hours of work for rest, exercise and recreation. His nervous troubles were of a functional nature, while his complaints about "queer" sensations in his head, after near use of his eyes, are evidence that he was straining them. His good health in old age, and his belief that "nervous troubles may be assuaged with advancing years," are only, Dr. Gould remarks, the philosophy of the presbyope who has not known the relief that comes to patients with eye strain, when the effort of accommodation has become impossible. Spencer did not overwork; on the contrary, he appreciated and advocated the value of rest and relaxation, but his ability "to read without glasses at the age of eighty-one" proves him to be and to have been a sufferer from compound myopic astigmatism. Insomnia and neurasthenia are often results of eye strain. Dr. Gould believes that properly adjusted glasses would have freed him from nervous troubles, and thereby made his life fuller, more satisfactory and more profitable.

RECOVERY WITHOUT TREATMENT FROM A MINIE BALL WOUND THROUGH THE STOMACH.

A CASE of peculiar interest from a surgical standpoint has recently come to light through the death of a veteran of the civil war. The man, who was in one of the volunteer regiments on the Federal side, was shot through the abdomen by a Minie ball in the second battle of Bull Run. He claimed to have lain for nine days on the battlefield without medical assistance, and afterwards to have been taken to a hospital in Washington, where he slowly recovered. He later re-entered the service.

In trying to obtain a pension on account of this wound, which later incapacitated him for work, he met with great difficulty, because of the natural incredulity of the authorities in the accuracy of his story, which the incompleteness of the hospital records failed to substantiate. It was not believed that he could have recovered and been capable of serving again as he claimed, if his own account of his injury were correct, and it was only a short time before his death that he received what would seem to be an adequate pension for so severe a wound.

His death recently has furnished an opportunity to verify his statements by postmortem examination, with the result that his case proves to be one of the most remarkable from a surgical standpoint

that occurred in the civil war. The autopsy was performed by Dr. Arthur W. Hopkins of West Swanzey, N. H., and Dr. A. R. Gleason of Keene, N. H. It was shown that the bullet entered the epigastrium one and one-half inches to the left of the median line, at the level of the lower border of the seventh rib. It penetrated both walls of the stomach and passed above the left kidney and pancreas, apparently without injury to either. It emerged a little to the left of the spine, where it lay beneath the skin, and, as the man frequently testified, was removed at the hospital in Washington, to which he was taken from the battle field. The scars left by the bullet in its passage through the body were clearly defined at the autopsy, leaving no doubt in the minds of the physicians as to the course it had taken. The immediate cause of the man's death was pulmonary hemorrhage, and his lungs were found much diseased.

It is probable that when the bullet was removed in Washington the surgeons concluded that it had in some way passed around and not through the body, since abdominal wounds caused by Minie balls in the civil war were almost uniformly fatal. Recovery in this case is due, almost without doubt, to the fact that the patient's stomach was probably nearly empty at the time when the bullet entered the abdomen, and that for nine days, according to his story, he lay on the battlefield without food and only with water given him by the rebels, who moved him to a sheltered spot and left him, as they supposed, to die.

Correspondence.

ATTENTION, HOUSE OFFICERS! SILENCE IS GOLDEN.

PADUNK, Feb. 14, 1903.

MR. EDITOR: I am impelled to write this note to you owing to two unpleasant experiences I have had recently in sending patients to one of the large hospitals of Boston, by the thoughtlessness of the house officer of that hospital. If you think it worth while, perhaps you will speak of it in your JOURNAL, that the matter may receive the attention of those in charge.

In one instance a patient who was suffering from acute appendicitis was seen by me in consultation. I advised his immediate removal to the hospital, which was done. He was operated upon and died. The house officer criticised the attending physicians who had sent the patient in to the relatives, saying that if that case had been sent in earlier he might have been saved. The man was sick three days, and it is obvious that I could not have advised his removal to hospital before I had seen him.

CASE 2. A patient was operated upon for septic finger, by amputation of the finger. I was called the second night after the operation for a severe secondary hemorrhage of the stump. I treated him as best I could and told him to go to the hospital the next morning, gave him a note to the hospital relating my experience, and suggested that he be kept until danger of secondary hemorrhage was over. He went to the hospital, and the assistant who dressed the wound laughed at my suggestions, sent the man home, and he promptly had another hemorrhage the next day.

I do not believe these criticisms by the young house officer or assistant are malicious, but simply thoughtlessness; they certainly are unpleasant to the attending physician, who often has no chance of meeting such animadversions.

Yours respectfully,

* *

RECORD OF MORTALITY FOR THE WEEK ENDING SATURDAY, MARCH 7, 1903.

| CITIES. | Population Estimated, 1903. | Reported deaths in each. | Deaths under five years. | Percentage of deaths from | | | | | |

Deaths reported, 3,194; under five years of age, 1,121; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 823, acute lung diseases 851, consumption 423, scarlet fever 35, whooping cough 57, cerebrospinal meningitis 6, smallpox 8, erysipelas 8, measles 24, typhoid fever 47, diarrheal diseases 80, diphtheria and croup 87.

From whooping cough, New York 6, Chicago 8, Philadelphia 7, Pittsburg 10, Providence 3, Boston 6, Cambridge 3, Lynn 2, New Bedford 1, Springfield 4, Haverhill 2, Chelsea 2, and Fitchburg, Framingham and Revere 1 each. From erysipelas, Chicago 2, Philadelphia 3, Pittsburg 1, Lowell 1, Marlboro 1. From smallpox, Chicago 4, Philadelphia 4.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Feb. 21, the death-rate was 16.7. Deaths reported, 4,841; acute diseases of the respiratory organs (London) 271, whooping cough 120, diphtheria 78, measles 94, smallpox 13, scarlet fever 49.

The death-rate ranged from 4.1 in Burton-on-Trent and Kings Norton to 24.1 in Great Yarmouth; London 17.6, West Ham 15.7, Brighton 18.7, Portsmouth 13.9, Southampton 15.2, Plymouth 11.2, Bristol 17.7, Birmingham 19.8, Leicester 11.7, Nottingham 15.9, Bolton 18.0, Manchester 19.9, Salford 21.0, Bradford 19.3, Leeds 16.3, Hull 15.9, New-Castle-on-Tyne 16.9, Cardiff 14.2, Rhondda 21.4, Liverpool 21.2.

METEOROLOGICAL RECORD.

For the week ending March 7, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

| DATE | Bar- om- eter. | | Ther- mometer. | | Relative humidity. | | | Direction of wind. | | Velocity of wind. | | We'th'r * | | Rainfall in inches. |

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING MARCH 12, 1903.

THOMAS, A. R., passed assistant surgeon. Granted leave of absence for two months from Feb. 25. March 5, 1903.

KERR, J. W., assistant surgeon. Leave of absence granted by Department letter of Sept. 20, 1902, amended so that said leave shall be for one month and fifteen days. March 2, 1903.

FOSTER, A. D., assistant surgeon. Upon the return of medical officer in command, relieved from duty at Wilmington, N. C., and directed to proceed to Charleston, S. C., and assume command of the service, relieving Acting Assistant Surgeon F. F. Sams. March 6, 1903.

DEAN, L. C., acting assistant surgeon. Granted leave of absence for two days. March 9, 1903.

GOLDSBOROUGH, B. W., acting assistant surgeon. Granted leave of absence for one day. March 9, 1903.

PATRICE, W. E., acting assistant surgeon. Granted leave of absence for fourteen days from Feb. 27. March 10, 1903.

RODMAN, J. C., acting assistant surgeon. Granted leave of absence for three days. March 7, 1903.

ACHENBACH, J., pharmacist. Relieved from duty at Port Townsend Quarantine, Washington, and directed to proceed to Port Townsend, Washington, and report to medical officer in command for duty and assignment to quarters, relieving Pharmacist R. F. Troxler. March 6, 1903.

THURSTON, E. J., pharmacist. To proceed to Gulf Quarantine and report to medical officer in command for duty. March 6, 1903.

WOODS, C. H., pharmacist. Granted leave of absence for twenty days from March 21. March 9, 1903.

DAVIS, H. E., pharmacist. Relieved from duty at Louisville, Ky., and directed to proceed to Memphis, Tenn., and report to medical officer in command for duty and assignment to quarters, relieving Pharmacist E. M. Holt. March 6, 1903.

TROXLER, R. F., pharmacist. Upon being relieved from duty at Port Townsend, Washington, to proceed to Port Townsend Quarantine and report to medical officer in command for duty. March 6, 1903.

HOLT, E. M., pharmacist. Upon being relieved from duty at Memphis, Tenn., directed to proceed to Louisville, Ky., and report to medical officer in command for duty and assignment to quarters. March 6, 1903.

PROMOTION.

Assistant Surgeon H. B. Parker commissioned as passed assistant surgeon, to rank as such from March 3, 1903.

RESIGNATION.

Passed Assistant Surgeon A. R. Thomas resigned, to take effect April 25, 1903.

CHANGES IN THE MEDICAL CORPS OF THE NAVY, FOR THE WEEK ENDING MARCH 14, 1903.

G. P. LUMSDEN, surgeon. Detached from the "Hancock" and ordered home to wait orders. March 9.

J. R. WAGGENER, medical director. Commissioned medical director from Jan. 20, 1903. March 10.

H. H. HAAS, passed assistant surgeon, and W. H. Bucher. Commissioned passed assistant surgeons from Jan. 10, 1903.

E. O. HUNTINGTON, J. B. DENNIS and E. THOMPSON, passed assistant surgeons. Commissioned passed assistant surgeons from Feb. 10, 1903.

B. H. DORSEY, assistant surgeon. Appointed assistant surgeon March 2, 1903.

I. N. HURD, pharmacist. Detached from the Navy Yard, Portsmouth, N. H., and ordered to Washington, D. C., for examination for retirement, and thence home to wait orders. March 11.

E. S. BOGERT, JR., surgeon. Detached from the Naval Recruiting Station, Buffalo, N. Y., and ordered home to wait orders. March 12.

P. F. McMURDO, acting assistant surgeon. Ordered to the "Gloucester."

W. P. GROVE, passed assistant surgeon. Detached from duty with Marine Detachment, Culebra, P. R., and ordered to Naval Hospital, New York, for treatment.

SOCIETY NOTICES.

CAMBRIDGE MEDICAL IMPROVEMENT SOCIETY.—A meeting in memory of the late Dr. Morrill Wyman will be held at the Colonial Club, Quincy Street, Cambridge, on Monday evening, March 23, at 8 P.M. Dr. H. P. Walcott will deliver an address, after which remarks will be made by President Charles W. Eliot, Dr. David W. Cheever, Dr. J. T. G. Nichols, Dr. William T. Conneliman and Dr. R. H. Fitz. All those interested are cordially invited to be present.

FRED R. JOUETT, M.D.,
Secretary.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—The society will hold a memorial meeting for the late Dr. John Homans at Sprague Hall, on Monday, March 30, at 8.15 P.M. Addresses will be made by Dr. Maurice H. Richardson, Dr. Arthur T. Cabot, Dr. George B. Shattuck, Dr. Edw. H. Bradford, Dr. Robert T. Edes, Dr. J. C. Warren, Dr. F. B. Harrington.

543 Boylston Street.

ARTHUR K. STONE,
Secretary.

RECENT DEATH.

DR. A. W. CHURCH of Waretown, N. J., died in St. Francis Hospital, Jersey City, on March 13, after an operation for appendicitis. He was thirty-three years of age and a graduate of the Edinburgh University and the Medical Department of Columbia University.

RESIGNATION.

DR. JAMES C. WHITE has resigned from the position of physician for diseases of the skin at the Massachusetts General Hospital.

APPOINTMENTS.

DR. JAMES C. WHITE, DR. WILLIAM L. RICHARDSON and DR. C. B. PORTER have been appointed on the consulting staff of the Massachusetts General Hospital.

DR. JAMES J. MINOT has been appointed visiting physician at the Massachusetts General Hospital.

BOOKS AND PAMPHLETS RECEIVED.

Proceedings of the American Medico-Psychological Association at the Fifty-eighth Annual Meeting held in Montreal, Quebec, June 17-20, 1902.

Diseases of the Stomach, a Textbook for Practitioners and Students. By Max Einhorn, M.D. Third revised edition. Illustrated. New York: William Wood & Co. 1903.

Surgical Anatomy, a Treatise on Human Anatomy in its Application to the Practice of Medicine and Surgery. By John B. Deaver, M.D. In three volumes. Illustrated. Vol. III. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1903.

Surgery of Penetrating Wounds of Lungs and Heart. (Experimental.) By Benj. Merrill Ricketts, Ph.B., M.D., of Cincinnati, Ohio. 1903.

Ligation of Arteries (Cocaine Anesthesia). By Benj. Merrill Ricketts, Ph.B., M.D., of Cincinnati, Ohio. Reprint. 1902.

Surgical Melange. By Benj. Merrill Ricketts, Ph.B., M.D., of Cincinnati, Ohio. Reprint. 1902.

Nasal Surgery. (Illustrated.) By Benj. Merrill Ricketts, Ph.B., M.D., of Cincinnati, Ohio. Reprint. 1902.

Lung Surgery. Historical and Experimental. By Benj. Merrill Ricketts, Ph.B., M.D., of Cincinnati, Ohio. Reprint. 1903.

EXTENSIVE CAVITY FORMATION IN THE CENTRAL NERVOUS SYSTEM, PRESUMABLY DUE TO *BACILLUS AEROGENES CAPSULATUS*.

BY EMMA W. MOOERS, M.D., WAVERLEY, MASS.

From the Laboratory of the McLean Hospital.

THE so-called Gruyère cheese brain has been the subject of much speculation since 1870. There have been various theories⁹ of the nature of these cavities found in the brain.

The earliest theory was that the condition is due to dilatation of the perivascular lymph spaces; later that it is a distention of the network of the neuroglia due to lymph stasis; again to dilatation of the pericellular spaces of the neuroglia or to absorption of the nerve substance from pressure. The process has been spoken of as "cystiform degeneration," also quite widely to-day as "cyst formation."

The other pathological conditions known generally under the term *état criblé* could hardly now be mistaken for that produced by the gas bacilli. In genuine cyst formation there is a lining membrane and evidences of a chronic process. At the present time there is no reasonable doubt that the cavity formation is due to the production of gas in the brain substance by gas-forming bacteria.

Bacteria have been found in the brain substance in this condition by several observers, but in only three cases has the identity of these bacteria been clearly established. Two of these cases are reported by W. T. Howard, Jr.¹ In one of them he identified the bacteria as of the species known as the *Bacillus aerogenes capsulatus*. In a third case reported by Madison⁶ the *Bacillus aerogenes capsulatus* and other bacteria were found.

The *Bacillus aerogenes capsulatus*, as first shown by W. H. Welch,⁸ is characterized by its power of producing gas in the tissues of man and animals. It is the bacterial cause of the majority of the septic and putrefactive conditions accompanied by gas formation in the tissues. It is a common inhabitant of the intestine, and is probably widely distributed outside of the body.

The *Bacillus mucosus capsulatus* is found in certain forms of pneumonia and peritonitis and in various other inflammatory conditions. It is probably a normal inhabitant of the upper air passages. The strain of this bacillus found by Howard in one of his cases was shown by him to be an energetic gas producer, both in culture media and in the bodies of animals.

The following case, which occurred at the McLean Hospital, may here be briefly reported. For the sake of brevity we leave out all detail which has no bearing on the special features to which we wish to call attention.

The patient, a man forty-nine years of age, had advanced general paralysis, having been in the hospital for nine years. He was profoundly demented, with extensive paralytic evidences, and confined to bed. He was well nourished and weighed 168 pounds. The patient's condition continued unchanged until a few days before death, when an increased restlessness was noted. On the morning of the day he died there was discovered a marked abdominal distention, a temperature of 104° and respiration 48-58. He rapidly failed, and died in the evening.

AUTOPSY. The autopsy was made twenty hours after death; the weather was hot and the body, with ice over the abdomen, had been kept in a cool room.

Rigor mortis was present; the face and body appeared bloated, the abdomen greatly distended and the entire skin of a dark bluish hue. On section there was gaseous emphysema of the subcutaneous tissues in both thorax and abdomen, but none in the scalp, which was very dense and of unusual thickness. Gas escaped on opening the abdominal cavity. The stomach and intestines were greatly distended with gas, and showed red discoloration in places. The blood vessels were very prominent. The liver appeared spongy, pale and puffy, riddled with gas cavities; the spleen slightly so. In the kidneys and heart muscle no cavities were seen; but both showed gas cavities and bacilli on microscopical examination. The heart muscle appeared soft, and on microscopical examination the muscle fibers were much fragmented and the nuclei stained poorly. The kidneys showed in places slight increase of connective tissue. There was no pneumonia, no pleural nor peritoneal exudate. There were old adhesions at the base of the left lung. The stomach showed several small erosions.

The brain presented at the autopsy nothing but the usual condition found in advanced general paralysis; that is, marked atrophy, especially in the frontal lobes (weight of brain 1070 gm.), thickening of the pia. The vessels appeared unusually large. It was put into formalin *in toto* and found to float. The formalin was frequently changed. The cord showed unusual thickening of the pia arachnoid from the thoracic region down and a marked dark purplish-red discoloration of the membranes.

After the brain had been six days in formalin, frontal sections were made. The appearance of these sections was very striking. The whole of the cut surface showed many cavities (Figs 1 and 2); these varied in size from 3.5 cm. to the smallest visible to the naked eye; the shape varied, being usually oval but sometimes round; a few were slit-like. They were located in both white and gray matter. The portions which had maintained the greatest integrity were the gray matter of the cortex of both cerebral hemispheres and that of the cerebellum. The basal ganglia and brain stem (Fig. 2) were equally affected with the medullary portions of the brain. There was present a distinct pigmentation in certain portions of the brain; it was of a dark slate color and irregularly distributed, being seen outlining some of the convolutions (especially in the temporal lobes) just below a narrow line of unpigmented cortex. This color was also seen in the gray matter of the cerebellum and irregularly on the cut surface of the pons and medulla. The cord below the medulla did not show this pigmentation microscopically, but in the meninges was seen the same dark slate color uniformly distributed.

MICROSCOPICAL EXAMINATION OF SECTIONS. Specimens from the cortex were hardened in alcohol and stained by Nissl's method. Other pieces were hardened in formalin and stained by hematoxylin-eosin and by Gram's and various other methods. Specimens from heart and kidney were hardened in Zenker's fluid.

The cortex showed the usual changes of general paralysis, which it is not necessary to describe here.

Of some importance, however, is the fact that the nerve cells presented no postmortem alteration, but throughout, the typical changes found in fever, namely, the uniform pale staining of cell bodies without reference to the stainable or non-stainable substance; this pale staining makes the processes visible much farther than normal; the axis cylinders are frequently stained. The nucleus is large with well-marked nuclear membrane, with moderately distended nuclear network, with now and then sharply defined irregular granules in the vicinity but not connected with the nucleolus. There is no pronounced increase of satellite cells. Beside the fever alteration, many of the cells, both large and small, show a yellow pigment situated irregularly in the cell body; individual particles of the pigment are not well defined in the Nissl stain. In a hematoxylin stained preparation, however, the pigmentation is much darker, being brownish with discrete particles.

The cavities in the brain tissue were found on microscopical examination without a living membrane; the walls were frequently smooth and clean cut, but there were many which looked slightly ragged in a part or the whole of the wall. The tissue around the cavities was composed of the brain substance itself; it showed no inflammatory reaction, though it often appeared compressed and took a slightly deeper stain; the nuclei were sometimes, but by no means always, paler in these zones. The larger cavities were empty or nearly so; somewhere along the edge of the walls of these were generally seen a few bacteria or an elongated mass of them; there were also found in some very fine shreds of tissue of the neighborhood, a blood vessel whole or ruptured and the contents of the latter. The smaller cavities almost invariably contained many bacilli, and in some was seen an amorphous substance containing sharply defined particles of dark pigment (iron reaction to this pigment negative). The cavities, while often showing some relation to a blood vessel, were seen also scattered through the tissue with apparently no relation to blood vessels or lymph spaces. Bacilli were found free in the brain tissue in clumps and singly, neither associated with blood vessels nor cavities.

Only one kind of bacteria appeared to be present (Fig. 3). These were bacilli of about the size and dimensions of the anthrax bacillus. They had round or nearly square ends, some of them stained somewhat irregularly, showing faintly stained areas in the protoplasm. In others were occasionally seen darkly stained granules. A clear halo could be plainly made out by partly shutting off the light, but no distinct capsules and no spores were seen; they were found in clumps, in short chains (rarely), in pairs and singly; the bacilli stained by Gram's method and by the ordinary aniline dyes. They are morphologically and in staining reaction identical with the *Bacillus aerogenes capsulatus* of Welch.

These bacilli, besides being found in the membranes, cavities and tissues, crowded in most places the small vessels so that often the blood corpuscles could not be seen. In the larger vessels they were also seen scattered through the contents and about their walls. Many bacilli were present in the choroid plexuses.

The other histological changes, namely, the altera-

tions in the vessel walls, the increase of cells and the presence of pigment granules in perivascular lymph spaces, the degeneration of myelin fibers in cortex and cord, the increase of neuroglia and the general disturbances of the normal architecture of the cortex,—all these are the changes commonly found in such an advanced case of general paralysis.

Spinal cord.—In the pigmented portions of the meninges, especially the pia arachnoid, the small dark particles of pigment observed in the brain were very numerous and sharply defined, being present in loose masses in the stroma, in the lymph spaces and within the vessel walls. The membranes contained enormous numbers of bacilli. There were well-marked cavities in the ventral fissure so that the adjacent structures were pushed aside (Fig. 4). There were a few very small cavities lying near clumps of bacilli, especially in the lateral columns of the cord; a few larger ones were found in the ventral horns; not all the blood vessels here contained bacilli, they were much more free from invasion than those in the brain. No bacilli were found in the central canal. The cavities were much fewer than in the brain.

In view of the large number of bacilli found in the brain and spinal cord of this case, and in view of the gas-producing powers possessed by the *Bacillus aerogenes capsulatus*, which we believe to be the bacterium concerned in this case, we agree with the view of other recent observers that the cavity formation in the brain and cord is due to the development of gas therein by the bacteria.

The question which, of course, arises in all such cases is this: Is this cavity formation in the central nervous system wholly a postmortem phenomenon? The absence of any reactive changes in the tissue and the absence of symptoms which would point to a sudden damage to the nervous system speak for this. But it must be admitted that the extreme paralytic dementia would have made such symptoms difficult to observe. Yet it is now well known that the *Bacillus aerogenes capsulatus* may invade the living organism, and Howard¹ and others¹⁰ have claimed that it may even cause acute purulent meningitis. Interesting in this connection is the case of Hartmann,³ in which the anatomical findings were those of extensive cavity formation in the central nervous system without any inflammatory or reactive process anywhere. In this case the clinical picture was very interesting. Some days before death there developed a most complicated group of both sensory and motor palsies with somnolence; there was distention of the abdomen, rapid respiration and elevated temperature. Nothing was found at autopsy or by histological examination which could account for the symptoms, except the presence of the gas bacillus in large numbers. Hartmann assumes that the cavities were formed postmortem, but that the presence of the bacilli in the nervous system, partly by their mechanical, partly by their toxic actions, caused the extensive symptom-complex.

In the absence of any other demonstrated cause of death in our case, and in view of the rapid and extensive abdominal distention with great rise of temperature, it seems possible that the invasion of the circulating blood by the bacillus was the cause of death by the production of a toxemia.

FIG. 1.— Frontal section through brain (in front of the crura), showing numerous gas cavities.

FIG. 2.— Section through pons and cerebellum, showing many cavities, especially in pons and white matter of cerebellum.

FIG. 3. — Section showing portion of one of the smaller cavities in brain. On the right, the wall; on the left, a portion of amorphous mass containing pigment granules and some bacteria; in center and wall, bacteria.

FIG. 4. — Section through cervical cord; large cavities in pia arachnoid, minute cavities in substance of cord.

BACILLUS SHIGA IN AN EPIDEMIC OF DIARRHEA.

BY LAWRENCE W. STRONG, M.D., WABAN, MASS.

For three summers a seaside community on the Maine coast has been disturbed by what were apparently epidemics of diarrhea, affecting both infants and adults, of varying degrees of severity, and beginning about the 1st of August in each year.

Often several members of one family were affected simultaneously or in succession, and only rarely was there anything obviously suspicious in the food which had been taken which might be regarded as a possible cause of the upset. The hygienic conditions of the village seemed well-nigh perfect. The water supply was a mountain lake situated about two miles from the village, two hundred feet above the sea level and from twenty-five to one hundred feet above the habitation levels, in depth averaging about one hundred feet, surrounded by forest, with but one house in its vicinity.

The milk supply was very largely taken from a milk farm on the shore of another lake, where the mountain lake water was used for the cattle and for domestic purposes. There was good pasturage in the meadows, the milk was cooled in ice immediately after milking, the stable and premises as well as the cattle and the attendants were as cleanly as the nature of the business allows. Bacterial counts of the milk made this year and last were comparatively low.

A new system of sewerage had been installed in 1901, whereby all waste was conducted in galvanized iron pipes to a cove at a distance from the village, and there discharged below low tide level. A few residences still discharged sewage into the harbor at tide level. Bangor and Boston markets furnished meats; vegetables were largely native grown, and consequently fresh. Climatic conditions were variable, there was a good deal of fog, as is characteristic of Maine, and this summer furnished an unusual amount of cold weather.

In analyzing this apparent epidemic it is not assumed that all the cases of diarrhea were of one form, even though an epidemic with a common cause may have occurred.

The common summer diarrheas are clinically separated into first, the simple diarrhea of nervous origin, or due to alterations in temperature, change in the food or other simple cause; second, the infective diarrheas, which are subdivided into fermented

diarrhea, cholera infantum and ileocolitis. This classification, while largely on the basis of symptomatology, takes a certain account of pathology and of etiology.

The simple diarrhea, which is non-bacterial, may, by increasing the susceptibility to invasion by micro-organisms, pass over into an infective diarrhea by allowing bacteria normally or accidentally present to invade the tissues. The infective diarrhea may be of the fermental type if the irritation acts high up in the alimentary tract, or it may produce an ileocolitis if the action of the bacteria or the absorption of toxic substances is delayed until the ileum or colon is reached. Thus a case may start as a simple diarrhea and end either as a fermental diarrhea or an ileocolitis. On this theory the same micro-organism, whether a normal inhabitant of the intestine or introduced with the food, might produce either a fermental diarrhea or an ileocolitis.

It is generally recognized that streptococci in the food, especially in milk, will produce diarrheas of the above types, and saprophytes also have been regarded as causative elements, but up to the present no definite relation has been found between any special form of bacteria and variety of diarrhea. Even if such a relation exists, it will hardly explain all the cases of infective diarrhea. As to the clinical classification of the cases actually encountered last summer, the majority were simple diarrheas of the non-infectious type. Then there occurred fairly numerous fermental diarrheas, the form which usually makes up 90% more or less of summer complaints, and what was most remarkable was a preponderance of ileocolitis, usually rather a rare condition. The greater number of these were rather insidious in onset, but developed in a day or two into a very obstinate and exhausting diarrhea, with numerous mucous and watery discharges, finally producing mucous casts of the intestine and bright red blood in specks and adherent to the mucus. Occasionally was seen a grayish or pink tinged slimy mass, apparently a slough from the intestine. In this form there was from the first a moderate continuous fever, from 100° to 103°, without morning or evening variations. Vomiting was common at the onset, but rarely persisted long. Tympanites and abdominal tenderness were common. The duration of these cases was variable, but the severer ones ran a course of one to several weeks.

Such cases as these, of which I had five under my own care, are the ones which suggest an epidemic, but in addition to these the mild cases were so prevalent that the inhabitant of this resort who escaped entirely was exceptional.

While the diarrheas were most prevalent and there was considerable excitement over the situation, Dr. Flexner visited the locality. Together with Dr. C. A. Herter and Dr. E. K. Dunham of New York an investigation was undertaken.

Cultures of the bacillus of dysentery isolated by Flexner from cases in the Philippines were obtained, and serum from one of my convalescent cases of ileocolitis gave a quick and marked clumping reaction with the bacillus. From the stools of another, most severe case, the same bacillus was isolated and identified. In this case injections of antitoxic horse serum prepared by Dr. Flexner from the bacillus of dysentery were used. This serum had been used

on animals with a protective effect and had been tested for ill effects on normal individuals, but had not been used therapeutically. Without stating any conclusions as to the use of the serum, the history of the case is given here for its bearing on the source of infection. The patient was a girl aged five, rather delicate and slender. For five days previous to her illness she had drunk nothing but boiled water on account of the suspicion cast upon the public water supply by the numerous cases of diarrhea. She drank no milk, but took a small quantity of milk on cereal food twice daily. The attack began rather insidiously and at first had the characteristics of a fermental diarrhea with severe vomiting and prostration, amounting to collapse on one or two occasions. Later bloody stools with mucous casts and rectal tenesmus set in. The child ultimately recovered after a most protracted illness. Further report of the case was made by Dr. Herter at a meeting of the Medical Association of New York City, when a paper by Dr. Flexner on the rôle of the bacillus of dysentery in the summer diarrheas of children was read.¹

As to the etiology, accepting Dr. Flexner's view, the bacillus Shiga is the causative agent for the case just cited, where it was isolated from the stools; in all probability also for the case which gave the serum reaction, and by analogy for the several other cases with a similar clinical picture.

Duval and Bassett isolated the same bacillus from the stools of forty-two cases of summer diarrhea in New York. The specific bacillus was not found in twenty-five healthy children, nor in children with simple diarrhea, marasmus or malnutrition, nor did the serum from the latter conditions agglutinate with the bacillus.

Duval and Bassett² do not state what type of summer diarrheas they investigated, whether fermental or ileocolitis, further than that they were bacterial and not simple.

As was stated above, the same organism may produce either a fermental diarrhea or an ileocolitis, according to the spot where the infected material lodges, but that this is invariably Shiga's organism can scarcely be maintained on account of the known rôle of the streptococcus.

Since it seems to be proved that Shiga's bacillus causes certain cases, the main question is, can we determine clinically which these cases are?

In all probability the serum reaction will afford the solution of this question, and in the absence of this we cannot venture conclusions as to this epidemic.

From a clinical standpoint there is nothing which separates the cases under consideration into groups or distinguishes those known or inferred to be caused by Shiga's bacillus from the others.

Only the cases of ileocolitis were tested for serum reaction, but ileocolitis is not enough to warrant the assumption that the bacillus Shiga is present, as the following case shows. A bell-boy, having eaten heartily of lobster à la Newberg, had a moderate diarrhea on the next day. This he aggravated by eating three bananas and drinking excessively of ice water. When seen at night time he had extreme rectal tenesmus, considerable mucus and

bright blood in the stools and marked prostration. No vomiting. Prompt recovery on symptomatic treatment. Here was evident food poisoning acting as a irritant in the lower bowel, with immediate recovery on removal of the cause, without the prolonged course characteristic of bacterial infection. Other cases of ileocolitis had an apparently simple beginning in a simple non-infectious diarrhea from improper food.

A girl aged four was taken on a picnic drive, and ate nut-cake and bananas. During the drive she vomited both bananas and nuts. The next day she was constipated, and the third day diarrhea set in, which did not become bloody for a day or two. The attack then went on to a most severe and obstinate dysentery, with a long course and a slow convalescence.

A boy of three, having eaten roast beef and spinach at noon, began to have movements at night containing undigested spinach. The following day he had six or eight movements containing undigested food. This diarrhea went on into a characteristic ileocolitis with mucous and bloody stools.

These cases suggest the possibility of the presence of Shiga's bacillus in the normal intestine, and that through the irritative action of a simple diarrhea from any slight cause or of a fermental diarrhea from infected food it overgrows the ordinary intestinal flora and sets up the inflammatory lesions of dysentery. Almost all the children's diarrheas, both ileocolitis and fermental, as well as several cases of acute gastritis, showed upon careful questioning some slight antecedent cause in the food sufficient to give the process a start, but once started there was no obvious reason why one should end as an acute gastritis and another as an ileocolitis.

Indeed, almost all the cases of ileocolitis had an origin in a gastric upset from improper food or in a fermental diarrhea, the facts speaking against the origin of ileocolitis as a primary condition, such as the invasion of a specific organism.

Although Duval and Bassett did not find the organism in the stools of healthy children, it cannot be assumed that it is not present there, being obscured by the colon bacillus. Shiga's organism appears to be a transition form between colon and typhoid, differing from them in its action on sugars, peptone and milk.

Shiga's organism forms no gas, forms acid on milk without coagulation but with a subsequent return of alkalinity. Shiga and Flexner report motility; Kruse and Duval do not. The formation of indol also appears to be somewhat in doubt.

Recent work has shown that this organism is viable in the soil even longer than the typhoid bacillus, and this suggests the means of distribution and production of epidemics.

Although definite conclusions are not justified from the fragmentary and inexact nature of the evidence afforded by these cases, the facts at least suggest that there must have been a common cause for a certain proportion of the unusual number of diarrheas encountered. Whatever the cause, it did not produce one characteristic form of diarrhea, although ileocolitis was conspicuous. The one positive bit of evidence afforded is that the bacillus Shiga was present in four cases of ileocolitis. If our clinical inference that some simple diarrheas

¹ Boston Med. and Surg. Journ., Nov. 27, 1902.

² Amer. Med., 1902, No. xi, 417.

passed into infectious diarrhea, and that the infectious diarrheas were either fermental or ileocolitis, according to the place of lodgment of the irritating matter, is correct, then the bacillus Shiga might be the common cause sought for.

The work of Duval and Bassett supports this view. This organism may have infected the soil of this locality from diarrheas occurring during previous summers. Its further transmission may be better studied here than in localities where the conditions are less simple. The water supply is almost unimpeachable, the only possibility of infecting it being from a farmhouse on its borders which is used as an inn. No case of diarrhea was reported from this house last year. Contamination of the water supply would not explain the case of ileocolitis in the child who drank boiled water exclusively previous to her attack, nor of a second child suffering from acute gastritis who drank Poland water exclusively. It seems much more likely that infection was spread by milk, since milk is more exposed to contamination and is an ideal *habitat* for bacterial growth. As was said, almost all the milk came from a single dairy within a mile of the village. Personal inspection showed careful handling and cleanliness, and bacterial counts of the milk on two occasions were low. Two severe cases of ileocolitis occurred in families using another milk supply.

Several positive facts, however, point to upsets from milk, although there is no known relation to bacillus Shiga. Two children aged twenty months and ten years respectively, sisters of the girl treated with antitoxin, were almost simultaneously attacked with vomiting. This occurred before the appearance of the epidemic of diarrheas. The younger child had eaten nothing but bread, butter and milk, the elder had a plain supper with milk. The third child, who ate the same food but drank no milk, was unaffected. The vomiting in both cases was intense, with prostration. These cases quickly recovered, the younger having diarrhea.

A boy of two and a half, who drinks Poland water exclusively, was attacked with vomiting, and retained nothing for twenty-four hours. The milk of the previous day was curdled when received. Recovery after calomel and saline. These cases prove nothing more than that milk, the chief food of infants, is very liable to cause upsets, and that this particular milk did cause such upsets. Many cases of diarrhea occurred in adults, who even if not milk drinkers used cream on food, and cream contains 90% of the bacteria of whole milk.

The insufficient evidence does not justify any conclusion as to the channel of infection, but there is more ground for suspecting the milk than any other source.

It is not necessary even to assume that the milk contained the bacillus Shiga when drunk, it is possible that the bacillus Shiga may be a normal inhabitant of the intestinal tract and that through some chemical or other peculiarity of the food it is enabled to overgrow its near relative, the bacillus coli communis, which usually is more florid in growth.

There may even be an analogy between the action of the colon and the bacillus Shiga on sugars and casein in the test tube and in the intestine. Since they are distinguishable only by their growth and

chemical changes on sugars, litmus milk and peptone, it may be these chemical differences which make the difference between normal digestion and a diarrhea.

A systematic search for Shiga's bacillus in the milk supplies of this locality is highly desirable. The stools and presumably the urine of all cases of infective diarrhea should be disinfected.

The locality considered here differs in no way from many others affected with epidemics of diarrheas or ileocolitis in the past. Last summer several other resorts suffered equally, although there was no connection between the places. The work of Duval and Bassett goes to show that summer diarrheas, common to every place, have a relation to the bacillus Shiga. Other work has demonstrated the wide spread of this organism in nature. Shiga's organism has generally been called the bacillus of dysentery. Duval and Bassett find it, however, in "summer diarrheas" without further specification. It was looked for in this epidemic only in certain cases of ileocolitis, meaning a diarrhea with bloody stools, rectal tenesmus and mucous casts. These may be properly called dysentery, but there was nothing in cause, onset nor clinical history to separate them from other summer diarrheas. The scope of Shiga's bacillus is not determined, it seems wider than dysentery, but not so wide as to include all infective diarrheas.

It is to be hoped that this report, far from deterring people from going to a favorite summer resort, will point out that all places are equally liable to experience such epidemics, and that this place, being better investigated, is better protected.

SYSTEMIC INFECTION DUE TO NATURAL TEETH CONDITIONS.¹

BY D. D. SMITH, M.D., PHILADELPHIA, PA.

THERE are in the human mouth today, as has been the condition through all the centuries, malignant factors of general infection, and causes of disease wholly unperceived and neglected, and thus the oral cavity has ever been and still remains a prolific source of contagion.

Medical science, and its allies, ancient and modern, virtually limiting study of the mouth, as an index to general systemic conditions, to the tongue, and naturally looking for ultimate causes of disease to inimical foods and drinks, or methods of ingestion; to so-called "malaria," to mental and physical overwork; to adverse locality, microbic atmosphere, morbid conditions of stomach, kidneys and lungs, has failed to apprehend or recognize agencies of infection, obvious, prolific and virulent, in the very vestibule of human life.

Dentistry, engrossed with its mechanics and mechanism, devoting its energies largely to repair of the teeth, has discovered nothing of the serious consequences of mouth infection upon general conditions; with magnifying glass and explorer searching for cavities of decay as its ultimate end, it has failed to discover the most important connections of the teeth in their relations to the general system.

¹ Read by invitation at the meeting of the Philadelphia County Medical Society, Jan. 28, 1903.

Hypothetical as these enunciations may at first appear, they will be found in the light of full scientific investigation completely verified.

The statement that all erupted or exposed tooth-surface, in its natural state, is bacterially infected surface, is incontrovertible. And when it is considered that in the normal mouth from eight to twenty years of age and later there are twenty to thirty square inches of such surface, the momentous import of these conditions becomes at once apparent.

To conceive of the oral cavity as the "vestibule of human life" is a simile not inappropriate, for it is at this entrance that all systemic stores, commissary supplies, fuels, etc., for nutrition, are received and tested on their way to the stomach,—the chief chemical laboratory and distributing center of the general system. And not only this—it is here that the various foods, solids and liquids, incorporate with the oral secretions piped into the mouth from special glands, and the mass is subjected to a process of maceration in preparation for deglutition. Engaged with these and other indispensable offices, the oral cavity is never wholly out of service, and literally, it may be said, it is never really cleansed. It is here that solid particles from the breath, saliva, food-remains and other débris constantly deposit and accumulate; becoming cemented to the teeth chiefly through inspissation of the viscid mucus perpetually oozing from many irregular glands beneath the mucous surface. Greatly augmenting the infection from this cavity, the air commonly diverted through it, especially in mouth breathers and in sleep, becomes a purveyor of toxic emanations to the lungs, where it inevitably deposits its contagion in lung tissue or the blood. Necessarily the subject of such conditions, this vestibular cavity with its twenty to thirty square inches of dentate surface becomes quickly infested and infected with all manner of bacterial formations, decomposing food particles, stagnant, inspissated, septic matter from saliva, mucus and sputum; not infrequently with pus-exudation from irritated and inflamed gum margins; gaseous emanations from decaying teeth and putrescent pulp tissue; salivary calculus (tartar), nicotine and the chemical toxins which result from decomposition due to mingling of mouth secretions, excretions and food-remains in a temperature constantly maintained at the high normal of 98° F. In this is presented a true picture of the innumerable sources of infection inseparably connected with untreated teeth. Incredible as it may appear, these conditions obtain, not in the lower classes alone, but in general mouth conditions in high and low born, fastidious and boor, king and peasant.

Respecting the state of the breath in ordinary expiration, Hermann Köninger, in the *Journal of Hygiene and Infectious Diseases*, summarizes some original experiments as follows:

"The author has been able to assure himself that in an apartment where there is no appreciable current of air, a person coughing or sneezing could scatter germs to a distance of more than 7 meters (22 feet). Germs are scattered through the air by means of salivary droplets. These droplets are really microscopic balloons, having a bubble of air in the center, and remain in suspension but a short time. The dissemination of droplets with their germ-originating capabilities and tendencies is most

marked during coughing and sneezing. The more pathogenic microbes the mouth contains, the greater the danger of infection. Washing the mouth has the effect of decreasing the diphtheria and other bacilli susceptible of being detached. Placing the hand or a handkerchief over the mouth prevents the emission of droplets charged with bacilli. During a surgical operation no one present should speak. Measures may be multiplied indefinitely for prevention in connection with this important idea of scattering infected droplets in the breath."

Thus it is manifest that with past and present conditions of mouth and teeth, infection in the oral cavity is a common heritage, and that none under the existing régime can wholly escape its evil consequences. A gleam of recognition of this fact is found in the *Lancet* of Nov. 15, 1902. The editor says:

"The alarming increase of dental disease is beginning to attract the attention of the general public, while there are also signs that the medical profession is becoming more alive to the possibilities of dental disorders being important factors in the production of certain general diseases. Dental caries is the most prevalent disease of the human race. There is little doubt that a large number of children suffer from impoverished nutrition solely from neglected conditions of the mouth."

Experience has shown that it is not only possible but entirely practicable, through intelligent "prophylaxis treatment," to successfully combat caries in children, and at the same time to keep the mouth in a good state of aseptis. An important auxiliary benefit from this treatment is found in its educating the child to intelligent self-care of the mouth, and in the relief it affords from the terrible dread and fear of the operations of dentistry, a present serious obstacle to proper professional care in all cases.

Recognition of this by physicians, to whose care children are naturally committed, and corresponding advice from them to parents or guardians, would result in incalculable benefit to the teeth and not less to the general health of childhood. The suggestion frequently seen, that the dental profession can or should assume to control the diet of infants and children for the production of good teeth, is an absurdity. If the dental or medical pediatricist had the power he would do well to give to every mother and every child a plentiful supply of healthful foods,—cereals, vegetables, fruits, nuts and meats,—and thus, and thus only, through dietetic means lay the foundations for good teeth. No special foods or special methods of feeding will accomplish this end. Foods that make good bone, muscle, nerve and other tissue, will likewise make good teeth.

If by "dental disorders" the *Lancet* means dental caries, which it styles "the most prevalent disease of the human race," it may be confidently questioned whether dental caries alone should be regarded "an important factor in the production of certain general diseases." Pyorrhea alveolaris (formerly styled Riggs' disease), an inflammatory condition of gum margins, pericementum, cementum and alveolar process, resulting in pus formation, and wholly dependent on the presence of natural teeth in the mouth, is unquestionably productive of some general diseases.

My observations lead to the confident belief that the kidneys are the organs affected by the products

of this particular pyemic condition. An error quite generally accepted for fact, is the belief that pyorrhea alveolaris results from uremic poisoning. While uremia and pyorrhea may be and often are associated, the presence of urea in the blood is not a cause of alveolar pyorrhea; but the converse of this proposition is a true pathological condition. Uremia is a usual result of alveolar pyorrhea, due to the perpetual ingestion of mouth toxins—pus and other effete products—which are constantly and inevitably taken into the stomach from this inflammatory condition *in the mouth*. Alveolar pyorrhea is never of systemic origin: it is wholly local and caused by the stagnant septic accumulations *on the teeth*. These accumulations induce inflammation of the tissues at the gum margins about the affected teeth, and as the inflammatory products increase, the gums, pericementum and alveolar tissue become involved and withdrawn more and more from portions of the roots, forming pockets which constantly increase the infection and hasten loosening of the teeth. Pyorrhea is readily amenable to intelligent treatment, when treatment is instituted before destruction of tissues has progressed to hopeless loosening of the teeth. An edentulous (toothless) mouth is never the subject of pyorrhea; and whenever the disease has developed, extraction of such affected teeth always results in speedy and complete cure. In this is clearly manifest the verity of the local origin of this disease. "The increasing prevalence of dental caries" surely cannot justly be held alone responsible as the cause of systemic disease; it is a factor, but only in so far as it contributes to general mouth infection.

To return again to the *Lancet*, if my interpretation of the article referred to is correct it would imply that "children suffer from impoverished nutrition" because of caries and inability to masticate food; this presentation should be received with caution. The facts are that with modern culinary methods neither perfect tooth mastication nor mouth insalivation are indispensable parts of the digestive process. True it is that free and comfortable mastication contributes greatly to the pleasures of taste and ingestion, and to that extent favors stomach digestion, but it is an office which can be delegated, as is often done, not only without injury but also with decided benefit. For the maceration of foods in the mouth, water and other customary drinks may be substituted for saliva without appreciable detriment; in many mouth conditions with advantage for the stomach. That saliva in the initial stages of digestion converts starch into sugar might have been a matter of more consideration before sugar entered so largely into foods and drinks as at present. Now, with a constant over-supply of saccharines, saliva, frequently vitiated and infected as it is poured into the mouth a direct secretion by the salivary glands, might in many mouth conditions give place to water in some form with advantage. We may regard water not simply as a food adjuvant and a diluent to the circulation, but as an integral part of nutrition; as necessary to digestion as to tissue replacement and to the maintenance of life. In this connection it seems reasonable to predict that the student of dietetics must soon broaden his field from the consideration of foods in their analytical ultimates, to embrace other and per-

haps more important matters in connection with their structural compounds. The demands of tissue building are such that we seem compelled to accept the fact that the real value of typical foods is dependent not so much on their ultimate chemical elements as on the value of the substance in its entirety, before the breaking up of the aqueous, vitalized compound-cells. Whilst fully aware that this may seem in conflict with the accepted physiology of digestion, it is a theory which is found to be in accord with everyday clinical experience and with conditions yet to be considered. The indifference of the stomach to mouth mastication and insalivation is clearly expressed in numberless cases of edentulous mouths; in these the processes of digestion and assimilation go forward regardless of tooth mastication, and with no apparent obstruction or derangement; and the remaining oral tissues in all cases will be found in perfect condition of health. It will yet be demonstrated that the real cause of general disease emanating from mouth and teeth is due neither to dental caries nor disability of mastication, but to constant and perpetual infection through septic matter in foods and drinks and the inhalation of toxic emanations from the presistent and abiding infection in mouths containing natural teeth.

"When does mouth infection due to the teeth begin?" It begins with the eruption of the deciduous set and continues with increasing gravity through the period of shedding the temporary and erupting the permanent ones, and thence on so long as the natural teeth are retained in the mouth; the most critical time being that of childhood and early youth, a period in which the mouth, under the present régime, is wholly without intelligent care. Children's mouths are frequently veritable crucibles in which are generated chemical agents and compounds, highly detrimental to the teeth themselves and not less to the general health of the child. Vitiated salivary and mucous secretions, bacterial plaques upon the teeth, decay, retained food-particles and saccharines; breaths loaded with emanations from stagnant septic matter, all at a maintained temperature of 98° F, insinuate into the circulation a constantly increasing infection, to find expression later in life in diverse pathological conditions, often in chronic and fatal disorders. It may appear, as it commonly does, in stomach or kidneys; in lungs or nervous system; in heart, brain or skin; in any organ or tissue to which mouth toxins are directly or indirectly conveyed.

In an endeavor to limit contagion, medical interposition very properly condemns expectoration in public conveyances, on floors, sidewalks and in all frequented places. Beards, kissing and even the shaking of hands, are under condemnation of the scientist.

The fact is that every mouth with teeth in natural *untreated* state is inevitably breathing out dangerous, infected droplets; contention, therefore, over the surgeon's beard or any other seems puerile. (Better if increased to a perfect mouth mask.) If discussion of it shall disclose the true source of beard infection, namely, septic mouth conditions, and emphasize the special dangers attending amphitheater and all surgical operations, through droplet infection, it will accomplish great good. We are now face to face

with the query, "Are these untoward mouth conditions remediable or must they endure?" The toxins engendered amidst stagnant accumulations perpetually adherent in the mouths of consumptives as well as the sputum itself in appreciable quantity clings to the already infected tooth surfaces, increasing bacterial plaques and multiplying bacterial cultures *in the mouth*. Can it otherwise be, then, that thus an endless chain of ever-increasing contagion revolves in foods and air to blood, thence to organs and tissues; to be deposited it may be as initial infection or perhaps in augmentation of some pathological state already established; or it may return to mouth in mucus or saliva; or in some inflammatory exudation, there to begin again its round of infection.

In 1894 I began a line of experimental investigation to determine the true source of tooth decay. Results from these experiments, carried forward on patients only, were all in harmony with the theory that caries of the teeth begins at some point on the exposed enamel surface, and that it is primarily due to affinities of the ultimates of the teeth for acids of the menstruum in which the tooth is perpetually enveloped. What seems indisputable proof of this theory is the fact that if a devitalized or pulpless tooth, such a tooth as is conceded to be the subject of more rapid decay than one with a vital pulp in the same environment, be removed from a mouth in which resolution is rapidly taking place, and if it be placed in water, alcohol or glycerine, or simply exposed in the air, all caries in that tooth is at once arrested.

The inevitable deduction from such an experiment is, that caries of the teeth is a result of environmental conditions, and this is in agreement with general observation and all clinical experience. Growing out of the experiments referred to, and their results, I have developed a system of caring for the teeth diametrically the opposite of all former conceptions, theories and methods of practice; and whenever the system has found typical exemplification, whether in childhood, youth, middle life or old age, most favorable and satisfactory results have universally followed.

The treatment consists of enforced, radical and frequent change of environment for the teeth, and perfect sanitation of all mouth conditions. Experience having demonstrated that the most careful and painstaking are unable with the agents commonly employed, as the toothbrush and dentifrice, tooth-pick and dental floss, soaps, so-called germicidal-washes, or other agencies, to effect this end, the plan of forcible, frequently renewed sanitation, by an experienced operator, has been instituted with results as stated. In detail, the process consists of most careful and complete removal of all concretions, all calcic deposits, semisolids, bacterial plaques and inspissated secretions and excretions which gather on the surfaces of the teeth, between them or at the gum margins; and this to be followed by thorough polishing of all tooth surfaces *by hand methods* (power polishers should never be used); not alone the more exposed labial and buccal surfaces, but the lingual, palatal and proximal surfaces as well, using for this purpose orange wood points in suitable holders, charged with finely ground pumice-stone as a polishing material. Treated in this

manner the teeth are placed in the most favorable condition to prevent and repel septic accumulations and deposits, and not less to favor all efforts of the patient in the direction of sanitation and cleanliness.

In every instance in which this treatment has been instituted for the deciduous teeth, and in many cases of adults, there has been immunity from decay, and the teeth have shown a marked change in structural composition. Alveolar development in children also has been apparently stimulated and increased, to meet requirements of the erupting teeth. The extreme and unnatural sensitiveness of the gums, attended with purple color, congestion and tendency to bleed, has in every instance been fully overcome, and there has been quick return to the normal condition of low grade sensibility, to the natural pink tint of the gums with their typical striations and beautiful festoons. It is also apparent that the tissues of the teeth themselves — especially the dentine and enamel — probably through stimulation of the vital forces of the pulp by this treatment, begin a surprising change for the better; a change which is first and specially noted in improved color and general appearance. Dull, opaque tooth substance often loaded with an offensive "old-ivory" pigment, is transformed into clear, translucent tooth tissue; the teeth assuming the appearance of living organs with an impressive individuality.

For seven years the revelations and the benefits of this treatment, hitherto unknown, have been to me a constant source of surprise and delight, and with ever-increasing emphasis it is demonstrating the necessity for this thorough and frequent change of environment for all teeth and all oral conditions.

To arrest or to prevent inflammatory process in the mouth is to arrest and prevent resorption of pus exudations and other effete products of mouth inflammations, which of necessity are carried directly into the digestive tract. The one and only method of prevention and relief from this source of infection is, as stated, forcible, complete and frequent removal of the stagnant irritants and toxics which perpetually recur on and between the teeth and along the gum margins. Maintained at intervals of about a month, this treatment is followed by immediate lessening and ultimate arrest of all inflammations and all inflammatory exudations from the oral tissues and complete eradication of the stagnant accumulations otherwise perpetually on and about the teeth. Another important beneficial result of this treatment is seen in the unloading of the breath of its malodors and consequently of its often malignant infection. Clinical experience adds its testimony in substantiation of all this. Of the whole number of cases under this monthly "prophylaxis treatment" all have shown some phase or state of general health improvement.

The most common condition—malaise—expressed in an indifferent appetite, coated tongue and sallow skin, has in every instance, in from three to four months, given place to clearing of the tongue and skin, better assimilation of food, and apparent increase of vitality.

Next in point of numbers are cases of so-called "nervousness," in both men and women — several in a condition approaching "nervous prostration." The rapid improvement and recovery in these cases has been a matter of astonishment and gratification.

inflammatory conditions of throat, some of long standing, and attended with tonsilitis, using topical applications only in addition to the "prophylaxis treatment," have in every case shown marked improvement; some have been cured and all others are improving under treatment.

One case of chronic nervous dyspepsia, in an inveterate smoker, complicated with violent paroxysms of acute stomatitis, in which the "prophylaxis treatment" was employed, resulted, after eighteen months, in complete restoration of mouth tissues, cure of the dyspepsia and return to full general health conditions.

In two notable cases of alveolar pyorrhea in men, in one of which a diagnosis of diabetes had been made, the "prophylaxis treatment" was instituted at intervals of two and three days for about three weeks, when the time was gradually extended to one treatment a week; and from that to one in two weeks, until at the expiration of three months there was a treatment every third week; topical remedies were mainly used. Both of these cases made a complete recovery both as to pyorrhea and general mouth conditions and the restoration of the general health.

In a case of long-standing tonsilitis, complicated with chronic inflammation of the upper pharynx, the uvula and the half arches, in six months under the "prophylaxis treatment," with topical applications to the affected surfaces, the patient was benefited to such degree as to warrant a most favorable prognosis.

Other and varied interesting conditions and cases which it is deemed unnecessary to introduce here have been greatly benefited by this "prophylaxis treatment."

It is a matter to be recognized that relief from mouth infection is to be afforded through dentistry alone. Germicides will not, they cannot accomplish it. There must be positive and frequent eradication of all septic conditions of the teeth, and all environmental conditions favoring toxic stagnation and germ culture in the mouth; and the after maintenance of the most perfect state of asepsis for the entire oral cavity.

It may seem difficult to realize, but it is nevertheless true, that no greater good could come to humanity through the medical profession than the full recognition of the dangers from this insidious, prolific and virulent infection in the human mouth.

The undisputed possessions of dentistry include the very gateway to the human system, with all the important offices attaching to it; and yet the profession has so circumscribed and limited its field of operations that it has to do chiefly with the one disease, caries in the crowns of teeth; and he that can the more adroitly deal with this condition is generally the most lauded. The limitations, feeble conceptions and the errors of writers and teachers have given the general public, and the great majority of the medical profession also, the impression that dentistry is what its schools have unwittingly made it, — first and mainly, the filling of a decayed tooth. Its want of standing with the community is such that in every conflict the medical opinion supersedes the dental. There is practically no finality in a dental diagnosis or decision.

The discoveries resulting from the "oral prophylaxis treatment" present the opportunity for greatly

extending the benefits of dental science and dental service, and for making the dental profession a branch of the healing art in reality; and this, in its own legitimate field, the oral cavity.

Is it too much to hope that in the beginning of this twentieth century we shall witness, from specially instituted chairs in schools of medicine and dentistry alike, teachings which shall make plain to both professions their true relations as to kinship, homogeneity and mutual interdependence; and which shall evolve a system of medico-dentobacteriological medicine having for its one object and aim the betterment of human teeth and the dethronement of mouth infection.

SUPPURATION OF THE FRONTAL, ETHMOID AND SPHENOID SINUSES.

WITH BRIEF REPORT OF THE TREATMENT OF TWO HUNDRED AND THIRTY-SEVEN CASES.

BY EDGAR M. HOLMES, M.D., BOSTON, MASS.

(Concluded from No. 12, page 312.)

IN my series the sphenoid cavity was diseased in 182 cases or nearly 77%, and in 19 or a little more than 8% of the whole number both sides were affected. In 56 of the sphenoid cases the ethmoid cells were found to contain and discharge pus, and in 3 all of the accessory cavities were suppurative. In 39 patients I was able to demonstrate pus in the ethmoid cells, and could prove no associated disease in any of the other sinuses. In 11 there was coexisting suppurative inflammation in the frontal sinus. In 5 cases of frontal sinus suppuration I was unable to prove suppuration of the ethmoid cells. As regards the relative frequency with which the sphenoidal, the ethmoidal and the frontal sinuses are found to be suppurative, my figures are not in marked contrast to the reports of many others, but during the period of these observations I have diagnosticated antral empyema in only 42 cases. I fear that many must have escaped me, as the great majority of pathologists as well as clinicians have found this cavity to be the more frequently attacked of all the sinuses. The fact that 61 of my cases consulted me for relief from ear trouble, and that every one in this class showed suppuration of the sphenoidal, of the ethmoidal or of the two combined, would account for quite an increased percentage of this class, but after removing these I still have over twice as many sphenoid as maxillary cases. In two of the frontal sinus cases I was able to detect through the naso-frontal duct with the probe roughened areas, which I took to be exposed bone, and in three cases after removing the outer wall of the frontal sinus, denuded bone could be seen as well as felt with the probe. In 89 of the sphenoid cases the probe came in contact with roughened areas, which I took to be exposed bone. Polypi extending into the nasal cavities were found in 26, into the ethmoid cells in 3 and into the sphenoid in 2 cases. In 13 cases I opened into cysts of the middle turbinate bone, finding pus in 9. In 5 of these cysts there were areas of necrosis, one having formed a communication with the nose. In one cystic cavity there

was a polyp which filled the whole space, and in another was a growth resembling a fine-grained tapioca custard. This under the microscope was said to be of a myxomatous nature. In one case I found a shoe button in the superior meatus which had remained in the nose for over twenty years, and in another case a sarcomatous mass, which was of the spindle cell variety and had invaded the antrum, the ethmoid and the sphenoid cavities. In 4 cases there was marked destruction of the septum nasi as well as necrosis in the sinus walls. There were present also other signs of syphilis in the mouth and throat, and I considered the sinus lesion to be a syphilitic process.

The symptoms of nasal sinusitis vary greatly in character and severity. A suppurative process may be present in one or more of the sinuses without local symptoms of sufficient severity to attract the patient's attention. Excessive secretion is a quite frequent symptom. This varies greatly in quantity and character. It may be chiefly pus or it may consist of a mixture of pus and mucus, and at times there is more or less blood. It may consist of lumps of pus suspended in mucus, or it may dry and form crusts which vary in color from a yellowish white to a greenish black. The secretion may be foul or it may be almost odorless. As a rule secretion from one side of the nose suggests either foreign body, local trauma, new growth, specific disease or unilateral empyema of one or more of the accessory sinuses. The patient may have the sense of a very disagreeable odor when others can detect nothing of it from the secretion. It may discharge mostly into the naso-pharynx, causing the symptom described as "dropping into the throat," or it may be mostly discharged from the anterior nares. There may be exacerbations of excessive discharge with intermissions of comparative freedom. These patients usually complain of having frequent colds in the head.

Pain is a very irregular symptom. In some cases of severe sinus disease it is absent and again it is so severe as to make life a burden, and resists large doses of analgesics. It is located and described so differently by different patients when the diseased area is the same so far as we can ascertain that, if given too much weight, it may mislead in making a diagnosis. There are certain characteristics, however, which are found of considerable service in helping to differentiate some obscure cases. When pain is due to eye strain it is usually worse after using the eyes. It is often absent in the morning or after a period of rest. Pain due to nasal disease is frequently worse in the morning and may become less later in the day. I have seen cases, however, which were cured of their pain by relieving an ethmoiditis when the use of the eyes increased the pain and when it was usually worse at night. Deflections and spurs of the nasal septum and foreign bodies in the nose may produce similar pain to that due to sinus disease. Pain of frontal sinus origin is spoken of as pressure at the base of the nose over the eyes of all degrees of intensity. It is frequently also associated with pain in the temples. Ethmoidal diseases may be accompanied by pain and pressure in the eyes, with a pressure described often as deep in the head. Occasionally there is frontal temporal and rarely suboccipital pain. When the sphenoid cavity is diseased and obstructed the pain is complained of

as deep and boring, and there is also almost always pain in the suboccipital region. It can be easily understood that pain as well as all symptoms of sinus disease is liable to wide variations, as the various cavities are so liable to be diseased at the same time, and as each cavity has been shown to vary in such a marked degree anatomically.

Mental depression is often very marked, especially in acute cases or during acute attacks of stenosis in chronic cases. The most marked depression apparently accompanies sphenoid and ethmoid diseases, especially the latter.

The symptoms pointing to the eyes often give us material aid. Beside the pain and pressure already mentioned there are functional disorders, as blurring, marked fatigue after using eyes, inability to overcome a small amount of astigmatism, diplopia, which may be spasmodic. Strabismus and ptosis may at times be present. Ethmoidal, frontal and maxillary disease may by direct pressure cause exophthalmos. Pressure upon the optic nerve may produce inflammatory processes of all degrees of intensity, which at times may end in atrophy of the nerve.

DIAGNOSIS.

It is often much easier to suspect a suppurative disease of one or more of the sinuses than it is to locate the site of the trouble, and when we have found one sinus to be diseased it may be hard to feel sure if one or more of the others are not also affected. The general symptoms already enumerated may be of great service in directing our attention in a general way to sinus affections and sometimes to certain cavities. Transillumination may be of service in examining the frontal and maxillary sinuses. We must not forget that a diseased cavity may have free drainage and transmit light as well as a healthy one, and that occasionally a healthy cavity transmits light very poorly; also, one or both frontal sinuses may be absent. Inspection of the nasal chambers through the anterior nares should receive our closest attention. There must be some system of procedure whereby each section is taken and carefully examined until every portion which the eye can reach has been inspected. This should first be done without clearing nose and without cocaine. When this has been accomplished cocaine can be applied, and after the mucous membrane has become contracted another inspection should be given. By these methods we find the condition of the mucous membrane whether hypertrophied or atrophied, and can discover if present deformities, cystic conditions of the turbinates, polypoid and other tumor growths, foreign bodies, dried plugs of secretion and pus. If pus is found we must, if possible, find its origin. We may find this only after several examinations.

Although the only positive diagnostic value of the location of pus is when it can be seen coming from a known cavity, yet when it is found to come from certain locations it is more or less suggestive of supuration of certain cells or groups of cells. When it is found to come from the middle meatus, it suggests trouble in the frontal, maxillary and anterior ethmoid group. If after cleansing, the middle meatus remains clear for some time and then pus appears after reclining the head to the other side, the antrum of Highmore is suggested as the source. Pus coming from the superior meatus about the middle tur-

binate suggests sphenoid or posterior ethmoid cell suppuration, and if the flow is increased by holding the head far forward, the sphenoid is liable to be the one affected. Pus may be so easily carried to parts of the nose remote from its source, either by gravity or blasts of air in sniffing or blowing, that only when we can see it discharge from a certain opening can we be sure of its origin. Much can be often gained, however, by shutting off certain areas with absorbent cotton. This procedure is also of service when we have found one area diseased and wish to stop its discharge to find if there be also a flow from other localities. When there have been distressing symptoms, together with a purulent discharge which does not subside under treatment, it seems justifiable to remove a part or the whole of the middle turbinate, after which it is often possible to more thoroughly inspect the openings from the various cavities.

The probe is, I believe, one of the most useful instruments we have in aiding us to explore cavities into which it is impossible to see. With it we can often detect granulations, ulcerated and denuded areas, and caries of the bony walls. While exploring a cavity we often produce pain, which the patient locates in exactly the area in which the pain associated with the disease is located. This fact is often of considerable value. The probe can almost always be used without removing the middle turbinate. It can be passed into the frontal sinus in about half of the cases and into the sphenoid in the great majority of cases. It should be very delicate, and should be used with great care when exploring the roof of the ethmoid and sphenoid cavities, and in fact to be of service must be used very gently over the whole mucous membrane lining of any of the accessory cavities, as it is easy to produce abrasions simulating ulcerations. It may also be misleading when it is in contact with dried secretion or with very brittle bone. It can, by changing the angle of the curve, be carried over practically the whole inner surface of the cavity under inspection.

The canula is another useful instrument through which the cavities can be cleansed or inflated. When used in stenosis of the naso-frontal duct, it often gives much relief to the symptoms as well as confirms a doubtful diagnosis. Before using either the probe or canula, the nasal cavities should be thoroughly cleansed.

Where pain and depression are prominent symptoms, the application of cocaine and adrenaline about the openings from the cavities may, by contracting the vessels in the swollen mucous membrane, allow better drainage and thereby give relief to the existing symptoms. When this has taken place, pus can sometimes be seen escaping from the affected area.

I have used, with considerable success, an instrument similar in action to Seigle's otoscope. It consists of a soft speculum tip which fits the nostril, a barrel with glass through which to inspect the interior of the nose, and a politzer bag with which to rarefy the air. The patient closes mouth and swallows when the compressed bag produces suction.

TREATMENT.

Of primary importance is the establishment of free drainage and the removal of all abnormal growths

and diseased tissue which tend to keep up the suppuration. In a large number of cases it is necessary to first remove a part or the whole of the middle turbinate, as this not only obscures from view the diseased areas we wish to reach, but prevents the introduction of instruments with which to remove the trouble in the more remote regions. This can be accomplished by first removing the anterior portion with a good cutting forcep and then separating the posterior portion with a snare scissors or cutting forcep. Large polyps can be removed by snare or forceps and smaller ones by a sharp curette. Diseased cavities must be opened by forceps drill, sharp spoon or some suitable instrument. All granulation and necrotic tissue should be removed as thoroughly as its location will permit. When possible the natural openings should be enlarged by removing portions of the bone about them. As a rule this is already diseased and brittle, and can be easily separated.

In all of these operations the areas should be as thoroughly cleansed and cocaineized as possible. The operation should occupy as little time as is necessary to accomplish the desired results, but of course great care must be used when working near the cribriform plate and at the roof of the ethmoid and sphenoid cavities. In the treatment of suppurative frontal sinus, much may be often gained by removing polyps or hypertrophied tissue about the infundibulum. The passage of the probe and the use of the canula may be of service. It seems doubtful if these are sufficient in severe cases, especially where there are extensive areas of ulceration, or polypoid formation within the cavity, and, when the symptoms persist after there can be found no internal obstruction to the normal drainage, some more extensive operation must be considered. Although it is possible to drill from the nasal cavity into the frontal sinus, and many operators advocate this route, yet as the sinus is often so extensive and the diseased conditions so advanced, the external operation offers much in its favor. Through such an opening the cavity can be thoroughly inspected, diseased tissue removed, sufficient communication established with the nose, and external drainage maintained until the more severe trouble is relieved. The safety and ease of this operation are strong reasons for its acceptance. The deformity following is the only strong argument against it, but if care is taken in making incision and in sacrificing as little of the superciliary ridge as possible, the resulting deformity in most cases is not marked. In operating upon the ethmoid cells, unless marked disease is found and it seems necessary to clean out the whole area at one operation, it often seems best to open up the area which is apparently most affected. If there is diseased tissue which is not removed and the symptoms persist, other portions may be reached at subsequent operations.

There are various forceps and curettes devised for the removal of diseased ethmoid tissue, but a small cutting forcep and three sizes of ring curettes are sufficient to remove the diseased tissue in nearly every case. The sphenoid can be reached by cutting away a portion of the anterior wall below the normal opening. Shaffer advocates a hook with which to tear away portions of bone. Grünwald uses a cutting forcep, and his method is easy and

sure in results. When forceps cannot be inserted into the normal opening, a drill can be first used and then the opening thus produced can be enlarged by the forceps. A sufficient opening should be made so that all granulation and necrotic areas may be reached and curetted if in a position where such a procedure is safe. Even a large opening may fill in and become closed in a few weeks and have to be again enlarged.

In the after-treatment the general as well as the local conditions must receive our attention. I shall speak here simply of the local treatment. For the first day after operation it is sometimes necessary to plug the injured areas to prevent hemorrhage, and when the patient is liable to be exposed to dust the anterior nares may be filled with absorbent cotton for two or three days. Where the discharge is not profuse, and where only small areas have been found to be diseased, it is not usually necessary to use washes or other local medication. Some of these cases are apparently well in ten days or two weeks. Unfortunately the majority are much more severely diseased, and it takes weeks or often months before the tissues are restored to such a condition that the symptoms and signs of disease have disappeared. Under the most favorable circumstances it takes a long time for large areas of exposed bone to become covered by a permanent membrane.

Where the pus is thick and liable to form crusts, it is well to have warm alkaline solutions used two or three times a day. A good instrument for using these solutions in the nose is a plain olive-tipped glass syringe. The patient's head is held forward so that all portions of the nasal cavity are below the level of the posterior nares, and the solution slowly forced into the nose from the syringe, the tip of which is inserted into the nostril. In this manner the whole cavity can be reached and cleansed without having to apply undue force. After this, as with any cleansing solution, care must be used about blowing the nose. After the nose has been cleansed an oily spray as hydrocarbolene, camphor, menthol and albolene or the like serves to soothe the membranes and give considerable comfort. Peroxide of hydrogen is often used and is highly recommended by some. I have used it with apparently good results in a number of cases. A half-strength solution of enzymol used morning and night after having first cleansed the nose has undoubtedly been of service in some of my cases.

Grünwald has obtained very satisfactory results in treatment of the sphenoid cavity by applying pure carbolic acid followed simply by irrigation.

The prognosis is of much importance, and in its consideration we have to take into account not only the local lesions but the resulting diseased conditions produced by them, as complications in these organs at times produce the more distressing if not the only symptoms. It may be possible to remove all trouble in the nose and yet get no improvement in the existing ear complication. The throat symptoms are almost always relieved if not entirely removed. Unless there has been extensive destruction with marked atrophy of the mucous membranes, a very favorable prognosis can be given, so far as the local symptoms are concerned. Even where there is atrophy with dry decomposing crusts accompanied by disagreeable odor, the prognosis is not necessarily bad. In fact

in the majority of these cases the distressing symptoms are relieved. Where they are not, there is doubtless an affected area which has not been reached by treatment. The more easily reached and the less extensive the necrosis, the sooner we may expect to get relief. The age and general physical condition of the patient, as in all processes of repair, play an important part. The pain is almost always relieved as soon as the pressure is relieved. There may be exacerbations whenever for any reason the opening becomes stopped. Pain in and back of eyes was relieved in 38 of my cases, 9 times in frontal, 23 times in ethmoid, and 6 times in sphenoid sinus disease. Six patients reported that they were able to dispense with glasses, which they had worn for mild degrees of astigmatism. One man had been obliged to wear constantly a +75 cylinder on the right eye and +50 cylinder on the left eye for over five years. He had been unable to leave them off for any length of time without severe headaches before operation. For a while the discharge may be increased after operation and this symptom be more pronounced. This increased discharge, however, lasts as a rule but a few days. Where there are large areas of denuded bone it may take weeks before there is complete healing, also when there are diseased areas near important structures which cannot be thoroughly curetted, the process of repair is retarded; again in such a spongy labyrinth as the ethmoid, it is easy to overlook one or more diseased cavities which may be sufficiently diseased to keep up a suppurative process.

In relation to polypoid formations, now that we are able to remove the diseased areas in the ethmoid, a large number of cases can be cured, whereas the simple removal of the polyps is in the great majority of cases only palliative. In eleven cases of polyps, where I removed the middle turbinate and all of the ethmoid which seemed to be diseased, there has been no return after a year. Eight of these patients had had polyps removed before, and some several times. I have had to operate upon eight the second time. In three cases new polyps seemed to form as fast as they were removed. The others of this series I have not seen and have received no reply to my cards of inquiry.

In the 16 cases of suppurative frontal sinus, 7 were relieved by removing obstructions in the middle meatus and draining the ethmoid cells. Four of these I was able to cleanse through canula, but into the other three I could not even pass the probe and could only cleanse about the opening of the infundibulum. Eight were apparently of a more severe type, and persisted after all internal treatment had been applied. Upon six of these I performed the external operation, and obtained good results in all but one. In this case both sides were diseased and there was extensive ulceration with much granulation tissue in the right sinus. There was free drainage into the nose on both sides, but the external wound remained open and discharged for nine weeks, when I again explored the cavity and removed a large amount of broken-down material. At the end of another eight weeks the cavity became closed, but there was marked deformity. Two patients refused to have an external incision, and in one the symptoms finally ceased to be troublesome, while in the other there have been

many exacerbations of pain with occasionally a discharge of pus into the nose.

In dealing with ethmoid suppuration there is such a labyrinth of cells, any one of which may be diseased, it is impossible to estimate with any degree of certainty the length of time necessary to produce a cure. Many cases where the symptoms are very severe and of long standing are relieved in a short time and others apparently less severe may take months. Fourteen in this series I discharged well in three weeks. Of the others 23 were well within two months, and 16 others within three months; 24 were apparently well after periods varying from three to six months, and 11 others after longer periods. The remaining cases were either not free from pus after long treatment, or after treating for a while, they failed to report for further examination.

The sphenoid cavity though large can be so thoroughly exposed and drained that the great majority of cases when not complicated are cured in a comparatively short time. In the 182 cases in this series there were only five of the non-complicated which were not cured by the end of six months. Two of these are discharging pus at present, although I can find no reason for it, unless, as sometimes happens, there is some small cavity which is diseased and communicates with the sphenoid. Eighteen cases were apparently well by the end of three weeks, 15 by the end of four weeks. Fifty-one cases were free from symptoms by the end of two months. Sixty-seven cases were under treatment between two and three months. Of the 26 remaining cases, 8 were discharged during the fourth month, 11 during the fifth month, and 7 during the sixth month. In nearly every case which was not free from symptoms by the end of two months there were either large areas of denuded bone or other cells were found to be diseased and discharging with the one under treatment. Even in the protracted cases the more severe symptoms as pain, pressure, dizziness, profuse discharge, etc., in the majority of cases, are quickly relieved.

As it is impossible to report individually from such a large number of cases in this paper, I hope to present, in the near future, many of the cases characteristic of the various classes.

Clinical Department.

MASSACHUSETTS GENERAL HOSPITAL.

(Continued from No. 12, page 314.)

DR. WILLIAM H. SMITH spoke on

INFLUENZA PNEUMONIA.

Dr. Cabot has asked me to say a few words in regard to influenza pneumonia as seen at this hospital. I shall limit myself to a brief discussion of the fatal cases. To Dr. Wright is due the credit of recognizing these cases, for as far back as 1896 he isolated the influenza bacillus from a case of broncho-pneumonia. The difficulty of recognizing these cases is great. First, because the bacillus is frequently found associated with the pneumococcus or streptococcus,

and in the routine cultures made at autopsies in cases of pneumonia blood serum tubes are used; the pneumococcus and streptococcus grow readily upon this media, while the influenza bacillus, although it may be present in abundance, fails to grow, as it requires a special media, one containing hemoglobin. Furthermore, some familiarity with the organism is necessary, as it is extremely small, and even in culture upon suitable media a hand lens may be needed to see the colonies. It is due, therefore, to these two facts, I believe, that more cases of influenza pneumonia have not been recognized, not because they are so uncommon. Since Dr. Wright's first case in 1896, there have been thirteen other cases of pneumonia coming to autopsy in this hospital from which the influenza bacillus has been isolated. There have been ten cases from the medical side and four from the surgical side shortly following operation. It is, of course, recognized that the number of cases is too small to permit of deductions, at the same time there are a few points of interest which may be mentioned.

The most striking thing, perhaps, noted at autopsy in these cases has been the tendency to the formation of multiple foci of consolidation, often widely separated from each other. Numerous areas of consolidation have been found throughout both lungs in several cases, or multiple foci have been present in one, two, three, four, or, as in one case, in five lobes. The size of these foci varies from pea to bean, or from the size of a chestnut to that of a pigeon's or hen's egg. The process may be a broncho-lobular, or by fusion of lobules may simulate a lobar pneumonia. A true pneumococcus lobar pneumonia may be present with an associated influenzal broncho-pneumonia. The foci may lie directly beneath the pleura, upon which is a thin protective layer of fibrinous exudate. Such foci may go on to abscess formation, and this fact has a clinical value, for it explains why a sudden pneumothorax may develop in cases of influenza; such cases have been reported by Mosler, Kundrat and Fürbinger. Furthermore, the patches of pneumonia are frequently present in the upper lobes, and given a case with the process thus situated, with slow resolution, with the accompanying temperature and purulent sputum, the diagnosis of phthisis may be made.

In all of these cases the bronchi were injected and filled with a mucoid or purulent secretion; on two occasions I cut up the entire bronchial tract, and found this purulent secretion even in the smallest bronchioles. Examination of this secretion shows it to contain chiefly pus corpuscles with desquamated bronchial epithelium, a few pneumococci or streptococci or both, but many influenza bacilli both within and outside of the leucocytes. Sections of the lung when stained and examined show the exudate in the alveoli to be made up largely of leucocytes, with varying amounts of fibrin, a few pneumococci or other organisms, but large numbers of influenza bacilli.

The age of the youngest patient in this series was two years, the oldest seventy-two. There is nothing characteristic about the pulse, respiration, or temperature, as may be seen by examining these charts (charts shown). Where the examination of the blood is recorded there was no leucocytosis, with the exception of one case, with an associated lobar pneu-

monia of pneumococcus origin; in this patient there was an increased white count.

The signs in the lungs may be those of a localized or a diffuse bronchitis, or there may be evidence of larger or smaller areas of consolidation. The rapidity with which such foci would appear at points in the lung widely separated from the original focus has been recorded. The following history illustrates this point well: A man of fifty-nine entered the hospital in January, 1899, with symptoms dating back eleven days, suggesting influenza. Upon examination at entrance no dullness or bronchial elements could be detected, many snoring râles were heard, particularly over both bases. Two days after entrance consolidation appeared at the right apex, twelve hours later there was a patch at the right back, and the expiration was harsh at both apices. Two days later consolidation was present at the left back. The sputum in this case showed both pneumococci and influenza bacilli. In other words, this patient entered with a bronchitis, after two days consolidation appeared at the right apex, twelve hours later at right back with suspicious signs at the left apex, and two days later a focus of consolidation developed at the left back. At autopsy eight days after entrance to the hospital, multiple patches of pneumonia were found at the right upper lobe, numerous foci in the right lower lobe and a focus the size of a hen's egg in the left lower lobe.

In closing it may be interesting to note that cases of influenza pneumonia have come to autopsy in the Massachusetts General Hospital in January, February, March, April, May, June, September, November and December, and at times when there was no epidemic of influenza recognized.

DR. F. E. LORD gave the results of his work on

INFLUENZA.

Through the courtesy of Dr. R. C. Cabot I was able, during the summer of 1902, to examine the sputa of many of his cases with cough and expectoration, in whom repeated examinations for tubercle bacilli had been negative. No discrimination was used in the selection of these specimens, and the series comprised acute and chronic coughs, both mild and severe.

In the first one hundred sputa, influenza bacilli were present in sixty, in large or small numbers; in twenty-nine of these sixty cases, influenza bacilli were in great numbers, and in practically pure culture in the fresh sputa. In all, the influenza bacilli were isolated from the specimens in pure culture on blood agar, proved not to grow on plain agar and to decolorize by Gram's method of staining.

Infection with influenza bacilli is therefore prevalent apart from epidemics.

Eleven of the out-patient cases were acute, eighteen were chronic.

Besides the eleven out-patient cases, eighteen acute cases have been analyzed from the house records. No house cases were included unless the diagnosis of influenza was confirmed by the presence of influenza bacilli in great numbers and in practically pure culture in the sputum.

The twenty-nine cases of acute influenza thus obtained were like epidemic influenza, except that the prostration was not so extreme. In their history and course they resembled other bacterial infections

of the respiratory tract, and the diagnosis was made with certainty only by finding influenza bacilli in great numbers in the sputum. Before the cause of their illness was thus determined, some of them were thought to have typhoid.

Twenty of these twenty-nine acute cases have been followed to determine the result of acute influenza.

Fifteen of the twenty had signs of bronchitis only. Thirteen of these fifteen recovered within six weeks. One still coughs with influenza bacilli in his sputum, three months after the onset of the disease. In a second, in whom the bronchitis was at first diffuse, there are now signs of localized bronchitis at the right base, but no influenza bacilli in his sputum, three months since onset. Five of the twenty cases had broncho-pneumonia. Two recovered after relapses and an illness of three and nine months. In a third, the solidification persisted for six to seven months, and this patient still coughs with influenza bacilli in his sputum, one year and nine months since he entered the hospital. The two remaining cases with broncho-pneumonia are dead. An autopsy was obtained on one, and sections of the lung showed influenza bacilli in large numbers.

Thus of the twenty cases, symptoms lasted for at least three months in five, and in one influenza bacilli are now present, after one year and nine months.

CHRONIC INFLUENZA.

Among the twenty-nine cases of influenza from the out-patient, eighteen have had a cough for months or years, with little variation in the amount, consistency or color of their sputum. Many of these chronic cases have been observed for months, one for a year and three months, and another for one year and nine months. Specimens of their sputa, obtained at frequent intervals, have shown influenza bacilli in practically pure culture.

These cases had been classed clinically as chronic bronchitis. It therefore seems that many of the cases formerly described as chronic bronchitis are chronic influenza.

The sputum of these cases has been purulent, usually tenacious and greenish in color.

Physical examination of these cases was negative in three. A bronchitis localized at both apices was found in one, a diffuse bronchitis in twelve, and broncho-pneumonia, as a cause of an acute exacerbation, in two.

Considerable change in the location and extent of the bronchitis was noteworthy in successive examinations.

Four of the eighteen cases with chronic influenza had attacks of paroxysmal dyspnea, for the most part nocturnal, but little influenced by climate or atmosphere. Nasal examination was negative in three. In one, Dr. Coolidge found chronic ethmoiditis, which may have had some influence on the attacks. Three cases showed no eosinophilia in a differential count of the blood. In these, the sputum has been greenish, purulent and constantly crowded with influenza bacilli, without eosinophiles, Curschmann spirals or Charcot-Leyden crystals. In the fourth case there were 5 to 10% of eosinophiles in the blood. The sputum contained greenish, purulent

masses in a colorless tenacious fluid. These masses contained influenza bacilli in great numbers. They have gradually disappeared from the sputum. In the tenacious fluid no influenza bacilli are now found, but there are great numbers of mononuclear eosinophiles and Curschmann spirals. This case must be regarded as coexisting asthma and influenza.

From the first three cases it may be that chronic influenza alone can closely resemble asthma.

The nose has been examined in nine of the chronic cases. No constant nasal disease has been established. Influenza bacilli were isolated in pure culture from the nasal secretion in two of the nine cases.

Chronic influenza is not infrequently mistaken for pulmonary tuberculosis.

Four of these cases at some time in the course of their illness had been sent to consumptives' homes. A fifth case was refused admission to a State institution for the cure of tuberculosis as too advanced.

CASES.

Ellsworth; sixty-eight. "Grippe," five years ago, and again four years ago. Yellowish green sputum since last attack. Under observation for two months.

Downing; sixty-one. Yellowish green sputum for forty-four years. Under observation for one year and three months.

Both patients have emphysema, diffuse bronchitis and probable bronchiectasis.

Their sputum, although frequently examined, has never shown tubercle bacilli. The tuberculin reaction was negative in both.

Their sputum has been constantly crowded with influenza bacilli.

Dr. Lord then showed two cases of chronic influenza.

The first patient, sixty-eight years old, had been under observation for two months. She had had "grippe" five years and again four years ago, with cough and abundant green sputum since the last attack.

The second patient, sixty-two years old, had been under observation for one year and three months. She had had cough and abundant green sputum for forty-four years.

Both cases were thought to have tuberculosis. Their sputum has been constantly crowded with influenza bacilli. No tubercle bacilli have been found in repeated examination, and they do not react to an injection of tuberculin. Both have emphysema, probable bronchiectasis and diffuse bronchitis.

Dr. R. C. CABOT: Two or three points seem worth mentioning. In the first place, this work is new, and it is very important work. The next thing that impresses me is the commonness of influenza outside of epidemics. It is very suggestive that sixty out of one hundred of these cases showed the influenza bacilla.

The third point is that these cases were considered as consumptive thirty or forty years ago. We can easily understand how simple it is to say that one has missed the tubercle bacilli, and diagnosed the case from the chronic cough and the emaciation. There was one case of this kind

refused admission at Rutland, the idea being that it was too far advanced.

Dr. F. C. SHATTUCK: Dr. Lord mentioned the fact that Curschmann's spirals were found in one case of asthma. I have a patient in my ward now who has the spirals, the first I have ever seen.

HERPETIFORM AND BULLOUS DERMATITIS.

Dr. R. H. FITZ showed the patient, a meat chopper, who, six weeks after having been vaccinated, wounded his right thumb while cutting meat.

A week later the wound became swollen and painful, and the patient had chilly sensations and was obliged to go to bed on account of weakness.

Groups of vesicles accompanied with itching then appeared on the back of the hands and wrists, and three or four days later bullae formed in large numbers upon the head, trunk and extremities. The blisters were as large as walnuts.

He entered the hospital nineteen days after the injury. There was a moderate elevation of the temperature, no leucocytosis, but 6% of eosinophiles. The bullae healed readily, and there was little or no tendency to ulceration. The epidermis separated from the feet like portions of a mould, and the new formation of epidermis on the blistered portions of the skin occasionally assumed a serpiginous character.

The case is of interest especially from its etiology. There was evidently a traumatic infection of an exceptional nature, and the appearances corresponded with those which have been observed in a limited number of patients after vaccination. Dr. J. T. Bowen has reported such cases of post-vaccinal herpetiform dermatitis, and there was one fatal case in the male ward last year.

Neusser states that a septic bullous dermatitis, usually fatal, has been seen in butchers whose fingers have been infected.

The nature of the lesions and the presence of the hoof and mouth disease in localities not far distant have suggested the possibility of the infection from this source. It is known that butchers have thus been infected when slaughtering the diseased

animals, although the hands and arms have been the seat of the eruption. There were no blisters in

A brother was humpbacked. She stated that her finger joints were noticeably enlarged a few

the mouth of this patient, but they have been absent in man where disease has been produced by wound infection.

The patient is convalescent and the disease has run an unusually mild course under the circumstances. Dr. J. H. Wright has made a bacteriological examination of the serum from the blisters, but has been unable to obtain any further information which might aid in throwing light upon the etiology of the patient's disease.

Dr. Fitz next showed a

CHONDRO-DYSTROPHIC DWARF.

The patient, forty-one years of age, unmarried, came under the care of Dr. E. P. Joslin at the House of the Good Samaritan with pains and stiffness in the hip and grating of the knee joints. She was referred by him to the hospital, that the nature of her deformities might be more accurately determined by means of the x-ray.

months after birth; that her deformities were apparent in childhood, when she wore apparatus to strengthen her feet and legs. She ceased to grow after the age of fifteen.

It is obvious that there is little or no deformity of the head and trunk while the arms and legs are so short that, as Dr. Goodall's measurements show, they correspond with those of a child of fourteen.

There is abundant fat tissue, especially at the knees, which are closely approximated; although the feet are widely separated there is no redundancy of skin.

The hands are stubbed, but the feet are not especially small. The former are abducted as in certain cases of arthritis deformans, and the feet show a definite talipes valgus. The motions of the hands and feet are restricted.

The skiagraphs make it clear that the shortening of the extremities is the result of disturbances in the growth of the epiphyses of the long bones, associated, also, with changes in the periosteal growth of these bones.

The head of the humerus is markedly enlarged while the shaft is short and narrow, causing a club-shaped appearance. The condyles also are enlarged. The head and tuberosity of the radius are enlarged, and from the lower edge of the former there is a sharply defined spine pointing towards the tuberosity. The styloid process of the radius is so enlarged, especially elongated, that the scaphoid lies nearly on a level with the os magnum, in consequence of which the abduction of the hand has taken place. The edge of the radial articulating surface is provided with a spinous prominence.

The top of the enlarged olecranon is represented by a sharply defined spine, and the styloid process of the ulna also appears enlarged. There is no evident alteration in the development of the carpal bones. The bones of the metacarpus and the phalanges are short; their epiphyseal ends, especially the distal, are decidedly enlarged. The proximal articulating ends are widened and thick-

ened, suggesting an increased periosteal growth of bone after the fusion of the enlarged epiphysis. The condyles of the femur and the head of the tibia and fibula are conspicuously enlarged, and a spicule of bone projects from the front of the tibia near the articulating surface. The tarsal bones are so enlarged as to simulate the appearances in acromegaly, and there are decided hypertrophy and irregularity of the epiphyseal end of the os calcis. The metatarsal and phalangeal bones of the feet show alterations similar to those observed in the analogous bones of the hand, the enlargement being most marked in the distal epiphyses.

The skiagraphs prepared by Mr. Dodd make it apparent that the shortening of the extremities is due essentially to an arrest of epiphyseal growth in length with a frequent luxuriant transverse growth in addition to an occasional protuberant growth. As a complication later in life there appears to have been the localized periosteal changes resulting from arthritis deformans.

The epiphyseal changes observed in this patient correspond to those described by Kaufmann as chondro-dystrophy. Cases of this affection often have been reported as fetal rickets, although it is now generally agreed that the process is quite independent of rickets, although its causes are wholly unknown. Sufferers from chondro-dystrophy as a rule die in early infancy and often are stillborn. This patient, therefore, is exceptional, though not unique as to age.

Although the deformities usually begin in fetal life and are apparent at birth, the evidence presented by this case indicates that the disturbed nutrition and growth of the cartilaginous ends of the

bones may first be recognized some months after birth. Another fact worthy of mention is that chondro-dystrophy has repeatedly been observed in cretinoid infants, and confusion has arisen in differentiating between infantile, sporadic cretinism (congenital myxedema) and chondro-dystrophy. This patient presents none of the deformities characteristic of myxedema or of cretinism.

(To be continued.)

Reports of Societies.

THE OBSTETRICAL SOCIETY OF PHILADELPHIA.

THE TREATMENT OF ECLAMPSIA, BY WILMER KRUSEN, M.D.

(Concluded from No. 12, page 320.)

THERE is one other form about which I am a little doubtful in my mind. I have seen two or three cases of this form which I have called fulminating eclampsia. This has been brought on by eating a large amount of indigestible food. One patient had eaten a lot of half boiled cabbage and grapes. There were no symptoms of headache or sign of toxemia. Another woman whom I saw in consultation about a month ago had eaten a large amount of pie. She went to bed with only slight indigestion and woke up in convulsions. These cases have had no previous histories, but after having eaten some indigestible food have had more or less indigestion, and have gone into eclamptic convulsions without any apparent toxic symptoms. I believe that if we watch our patients there will be very few cases of eclampsia, and that the cases can be much better treated before the eclampsia occurs than after. I would lay special stress upon the amount of urea in the urine. My experience is that when this gets below 1% the woman is in danger, and should have small doses of calomel grain one-tenth to grain one-fourth three times a day with a milk diet.

Regarding the general treatment, I have nothing to add, except that in my experience veratrum viride has done well, especially in ten-minim doses repeated. I also believe in the use of salt solution. In the matter of delivery, my experience teaches me that the more quickly the child is delivered without undue violence, the better. Time should be taken to dilate the cervix. This can best be done with fingers in a large number of cases. I have not used Bozzi's dilator, but from examining it would think that the cervix would be torn if dilated too rapidly. I am especially fond of using the McLean bag. This can be put in the cervix, and with a good piston syringe I can dilate the cervix in an hour. If the cervix is very rigid it may require three hours for dilatation. It is not only for the sake of the mother, but for the child that delivery should be brought about; for if the child is kept in a woman having convulsions it will almost invariably be lost, and if delivered will die of toxic symptoms very much resembling those of the mother. My experience in raising children born of eclamptic mothers has not been very successful, only three or four out of a great many cases having lived.

DR. JOHN C. DAcOSTA: As Dr. Barnes said, there is such a diversity of opinion as to the etiology of eclampsia that one is at a loss to form the true idea

of the causes. There may be a variety of causes. The keynote of treatment was struck in what Dr. Krusen said about prophylaxis, and especially in what Dr. Coles said about the preventability of eclampsia. I go farther than Dr. Coles, and think the cases can be reduced more than 90% if the patient is treated in time. I believe a great deal of the mortality and many of the cases of eclampsia are due to neglect of the patient. The patient calls upon her doctor, engages him and sends for him when about to be confined. To use a homely phrase, you would not take a horse out of a stable, put him upon the race track and expect him to win. You train your horse beforehand, and then expect him to win. Train your woman for six weeks or two months before her labor, and the number of cases will be reduced more than 90%.

What Dr. Norris said I think was a very important point; that is, we should not only know the percentage of urea eliminated, but the amount in grains eliminated per diem. You may have 2% of urea and a woman passing only 8 to 12 oz. of urine a day and loading herself up with toxic products, and she may have convulsions. Train her two months beforehand, so that the excretory organs are in good working order. Restrict the diet, examine the urine weekly for albumin and urea, and the amount of urea. If a convulsion occurs, the best treatment is to empty the patient's stomach, bowels and bladder, and, as Dr. Coles has suggested, get the baby out as quickly as possible without any undue violence. After all this, if convulsions continue (although I know veratrum viride is a very useful agent, you don't have time to use it), I am a firm believer in the value of the lancet. If you have not your lance with you, you have your pocket knife. I have seen a number of cases of puerperal convulsions in consultation, but have never had such a case in my private practice, probably because I do not care to attend patients unless I have had them under my care for a couple of months. I do not regret a single case in which I have been allowed to bleed, but do regret every case in which I was not allowed to bleed. Over twenty years ago I was struck with the remark of a prominent practitioner upon the value of venesection. While a resident in Blockley he had made post-mortem examinations of twenty patients dying of puerperal convulsions, and in nineteen of these found a big clot of blood in the brain.

When you have the dry, hot skin and the quick, irritable pulse and put your lancet or knife into the arm you often do not get any blood. You have to manipulate that hand and arm, and then you get a great tarry string before you can get any blood to flow. You should bleed that woman until you get the pulse down in speed and up in power. She will probably then get well.

DR. L. J. HAMMOND: I have not for some years been much interested in obstetrics, though I have had a very large experience, much larger than I desired, in the treatment of eclampsia. Two conditions that I have especially observed are that: first, eclampsia occurs in pregnant women who have previous to the pregnancy been subjects of nephritis; second, there is a condition of eclampsia which develops in pregnant women who have not been previous to pregnancy subjects of kidney disease,

but who during the course of pregnancy, and I believe dependent upon it, develop acute nephritis. In those cases in which the pregnancy followed the kidney disease, so to speak, we invariably have the most serious form of eclampsia to deal with. Those in which we have, as several gentlemen have spoken of, a condition that seems to be an involvement of the liver, but which I always felt was in reality the result of the nephritis rather than a change of the hepatic structure; in other words, the hepatic condition was the result of and not the causative factor in the production of these various abnormal systemic conditions. In support of this I may say that no case of eclampsia has ever come under my observation where the clinical picture of nephritis did not foreshadow all other organic lesions. For this reason, and in view of the fact that the various hypotheses have no definite conclusions as to the etiology other than that it is due to nephritis, and in view of the fact that decapsulation of the kidney has been effective where prophylaxis has not been satisfactory in conditions due to parenchymatous change, in other than pregnant women, I would ask, would it not be good practice to do the operation of decapsulation as a radical prophylactic measure when the more conservative prophylaxis seemed not to lessen the dangers of eclampsia at the sixth or seventh month, or as early as could be done if one felt confident that the kidney change existed prior to the pregnancy. It seems to me that such favorable results have been reported from the operation of decapsulation that I see no reason why it should not be considered in connection with these very depressing conditions associated with pregnancy.

DR. HOPKINSON: The subject has been so thoroughly gone over that there is not much to add in reference to the etiology of the disease. We all agree with the writer that it is very obscure, and it seems more obscure to me to-night than ever before. The thyroid treatment opens up a new field, which we ought to try on account of its harmlessness. The Stroganoff treatment has been mentioned. I have employed it in five cases without mortality. I regard the use of oxygen superior to that of chloroform. Chloral, I think, is a valuable drug in this disease, and when given with morphia we can avoid the eliminating processes, sweating, purging, bleeding or the salt solutions, etc.

I look upon eclampsia as an acute infectious disease of rather short duration, rarely lasting over forty-eight hours.

In reference to emptying the uterus, I have never used that forty dollar instrument, I prefer the fingers for dilating. It takes about an hour to dilate the cervix and another hour to dilate the lower segment of the uterus. That is the time I would usually consider the safe limit in *accouchement forcé*, especially in primiparæ.

I would like to hear more about the use of chloral. This, I believe, is used largely by the French, morphia by the Germans. Stroganoff treatment combines the two.

DR. GEORGE H. BOYD: I think we owe a debt of thanks to the essayists for the interesting and exhaustive papers on eclampsia. We could probably discuss the subject until midnight and be enlightened in some respects and yet be a little farther from the solution in the end. There is no doubt

but that we can do most by prophylaxis. If we can follow our patients through pregnancy we will not have cases of eclampsia. I agree with the remarks made by Dr. Norris regarding the hygiene of pregnancy, involving the care of the bowels, diet and exercise which will avoid the result of eclampsia. We do not know what produces the toxemia, and we do not know what drugs to use in its treatment. I think it is a great mistake to lay great stress on any one drug. Dr. Norris speaks highly of *veratrum viride*. I have used it for five or six years, and find that it is more of a depressant than other drugs of its character. I feel convinced from my practical work that it is a good thing to empty the uterus, and I believe the best dilator is the fingers. The drugs which seem to me to be chiefly indicated are chloral and morphia, with chloroform for the convulsions, but am still doubtful as to the efficacy of any medication in this disease.

DR. D. E. LONGAKER: It seems fitting that the importance of the medical treatment of eclampsia should be emphasized. I am confident that it is not a mistake to treat the convulsions first, and I am sure that the best results will be obtained in this way. We know that in probably one third of all cases of eclampsia the convulsions first occur post-partum; and, where the convulsions occur before delivery, late in pregnancy, without any sign of labor, I am convinced that I have seen the most disastrous results occur by precipitate delivery, probably neglecting the medical treatment. In such cases, by all means treat the case medically. Treat the convulsions; treat the case surgically, obstetrically afterwards, but by all means arrest the convulsions. Chief and best of the medical agents in my experience has been *veratrum viride* systemically used to the amount of probably five to seven drops of the tincture or of the liquid *veratrum viride* used probably at fifteen-minute intervals until the pulse is brought below 60. I believe it is the rule that when the pulse is kept below 60 convulsions do not occur. Some years ago one of the fellows of the American Gynecological Society went into the subject of the treatment of *veratrum viride* rather exhaustively, with the result of recommending it most highly when used systematically in this way. Next to *veratrum viride* the chloral and bromide administered by the rectum I have found valuable, to the amount of dram doses of the chloral and proportionately as much of the bromide. Next to these comes the eliminative treatment and one drug which I have found of value used over a long period is elaterium. In my experience the results are better under energetic medical treatment than under the more radical surgical or obstetric.

DR. BARNES closes: I am glad for two or three reasons that the discussion turned chiefly upon treatment; first, because of its more immediate practical importance, and because we cannot settle the question of etiology in one evening; and, second, because there is not so much for me to respond to so far as etiology is concerned. One of my acquaintances has the honesty to say that he is even more confused since my paper in regard to the etiology than before. I shall not feel elated, but I have such a sense of the humorous that I am more pleased than injured. I shall take the more agreeable consideration, thinking that he means that we cannot

comprehend the question of etiology, and that when we discuss a difficult question we all do feel more perplexed than before. In regard to the inhalation of chloroform during the convulsive seizures, I have used it and seen it so used that it was valueless; that is, the administration would be begun after the spasm had assumed the onset. The convulsion must be anticipated if it is to be modified or controlled.

Dr. Norris seemed to belittle the value of examination of the urine, but later said he depended upon it to determine the amount of urea. We may have a normal amount of urea, but in following the patients possibly find toxic symptoms regardless of this. We need to watch and guard our patients. Predisposing causes must be understood, the excretory organs and the nervous system. Our patients must be constantly interrogated. Dr. Norris also said that anemia had oftentimes a close proximity to toxemia. I have a patient now who seems to illustrate that fact. The woman has given birth to children rapidly. A child was born a year ago, and on last Sunday another was born. The one born a year ago was weak and died, and the burden of caring for that while carrying the one just born was a great drain upon her strength. A few weeks ago she had an attack of the grippe, and following that she was especially toxemic, with a low percentage of urea and some hyaline casts. She tried to go into labor but was becoming irritable and worn out. Her condition emphasized the value of the rubber bag. This was introduced and remained in for several hours. She had considerable pain; the cervix was two thirds dilated. I felt that this was much better accomplished than by hand. She subsequently delivered herself promptly.

Dr. Hammond speaks of the cases which previously had nephritis as being the most serious. I think that the purely toxemic type is the more dangerous. They are more serious because the onset is insidious and they become very toxemic before the condition is recognized. In those cases in which nephritis previously existed and is recognized, the physician is on his guard.

In regard to the statement that one third of the cases of eclampsia occur post-partum, I think that statistics will show that a little more than one fourth occur before the onset of labor, about one half during labor, and less than one fourth postpartum.

Dr. KRUSEN closes: As I said in the beginning of my paper, I think it has been pretty clearly demonstrated that there are mooted points in the treatment of eclampsia. Dr. Norris has emphasized the importance of the examination of the urine in estimating the amount of urea excreted, and commended the use of drugs stimulating the action of the liver and kidneys. In regard to venesection, I am sorry I did not use it in cases in which I employed veratrum viride. It is not to be supposed for one minute that we would bleed a poor miserable anemic woman. I can hardly think either that one would give veratrum viride in such a case. There are positive indications for each remedy. Morphia I have found to be a good drug. We have to consider the practical side of these questions, employing the method practical under the circumstances in which we are working. It is not to be supposed either that I would give chloroform during a convulsion. It is to

be given when we see the little twitching signs, the rolling of the eyes, etc., and about thirty seconds or a minute before the true convulsion appears.

Dr. Coles spoke of the different forms of eclampsia. This is an interesting point. In the treatment of eclampsia I did not have time to consider the different forms in detail. In regard to the use of veratrum viride I think it makes a difference whether Norwood's tincture or the ordinary tincture is used.

Dr. DaCosta spoke of the character of the blood. That is often noticed and is one of the evidences in profound toxemia of the changes that take place in the blood.

I think Dr. Hammond's remarks form another evidence of the prevention of apoplexy. It does not matter so much as to the amount of blood that is drawn, but as to the effect upon the pulse.

In regard to Edebohls' operation, I had thought of that after reading papers on decapsulation of the kidney, but I do not know that any obstetrician has had the courage to perform it during pregnancy. If, however, it is indicated in acute Bright's disease, why should it not be indicated in the condition under discussion?

Straganoff's name seems to be closely associated with eclampsia, and I have often wondered whether his statements were absolutely accurate, because it seems to me it is wonderful to report such a very slight mortality. There is no American obstetrician who can give statistics compared to his.

Chloral I did not mention because I do not use it. Morphia I find takes its place. Why should I give chloral and sodium bromide if I can get rid of the nervous irritation as quickly by morphia? It is often impossible to give anything by the mouth, and if given per rectum is apt to be expelled by the convulsive action of the patient. It also interferes with the injection of salt solution, which I feel to be valuable in these cases. The method of dilatation I have always employed is that of manual.

Recent Literature.

A Manual of Dissection and Practical Anatomy Founded on Gray and Gerrish. By WILLIAM T. ECKLEY, M.D., Professor of Anatomy, and CORINNE B. ECKLEY, Demonstrator of Anatomy in the Medical and Dental Departments of the University of Illinois. In one octavo volume of 400 pages. Illustrated with 220 engravings, 116 of which are colored. Philadelphia and New York: Lea Brothers & Co., Publishers.

This volume is essentially a condensation and rearrangement of the works of Gray and Gerrish, planned with particular inference to the needs of dissecters. The subject is taken up from the standpoint of regions, many less important details are omitted and the student is afforded a quick, and for the most part adequate, means of reference. Such an arrangement has many advantages for the practising physician over the more systematic plan of the larger books. The illustrations are numerous and excellent, and also familiar, since they are taken in great part without alteration from other books. The size of the volume is a recommendation.

THE BOSTON

Medical and Surgical Journal

THURSDAY, MARCH 26, 1903.

283 WASHINGTON STREET, BOSTON, MASS.**THE GRADING OF DEFECTIVE PUBLIC SCHOOL CHILDREN.**

ONE of the serious problems of our public school system is the proper classification of pupils. It is inevitable, in a large city in which pupils must be taken from varying classes in the community, with a large admixture of foreigners, that different degrees of intelligence in children of approximately the same age must be frequent. Particularly difficult is the question of the proper classification of those children who are congenitally backward in mental development, or who are actually deficient and wholly incapable of acquiring rudimentary knowledge.

These difficulties have naturally been for a long time recognized, and in some instances different measures for the improvement of the conditions have been undertaken. In Boston, for example, according to the twenty-second annual report of the superintendent of public schools, three special classes in the schools for the instruction of mentally defective children have been in existence for several years, but have attracted little public attention until very recently. Since the publication of this report, two more classes have been formed in outlying portions of the city. These classes are naturally recruited from the ordinary classes, largely through the judgment of teachers who find certain pupils incapable of keeping up with the average. As the matter has attracted more and more attention, the attempt has been made to classify these defective children under three general types: first, true imbeciles, who are wholly unfitted to be kept in public schools; secondly, somewhat feeble-minded children, who are practically unimprovable under ordinary class room instruction; and, thirdly, children who come within normal limits, but who are exceptionally dull and who require special instruction. It is evident from

the medical point of view that anything like a strict classification into these three classes is extremely difficult and often impossible. As a working basis, however, it is in general to be commended.

The so-called special classes, to which we have already alluded, are designed for children of the second type, namely, those who are feeble-minded and incapable of improvement under ordinary classroom conditions. Such children for their own good and also for the good of other pupils should be under the instruction of specially equipped teachers. It should also be recognized far more than is at present the case that the teaching of these children is an extremely difficult although by no means a thankless undertaking, and should be entrusted to teachers of very exceptional training and qualifications. Such teachers are, fortunately, under present conditions obtainable, although not always easily. For children of the first class it is clear that the public school is in no way adapted. They should be treated at special schools for imbeciles, an admirable example of which we have in this State at Waverley.

More important perhaps than the special classes are classes which should be connected with all grammar schools, which may be called ungraded classes. These are for the purpose of giving special instruction to pupils whose mental processes are slow, and who are, therefore, not able to compete with their fellow students. The importance of this type should be very clearly recognized, and should not be relegated to the position of a class to which poor scholars are sent, regardless of their future mental development. According to the superintendent's report, to which we have referred, the error has at times been made of assigning highly unskilled teachers to these somewhat, from the general point of view, uninteresting classes, rather than selecting with great care the instructor who has a particular aptitude for this most difficult and, therefore, in a sense, desirable teaching. Many of these ungraded classes are, undoubtedly, admirably managed and admirably taught, but there still seems to be a certain necessity for the recognition of the fact that everywhere and in all classes special attention should be given to these pupils who with care may undoubtedly make not only useful but entirely intelligent men and women. It is also to be borne in mind that many of these pupils, by special training, may again be restored to the regular graded classes.

The whole matter evidently has a very direct medical bearing, and one in which physicians in general should manifest a high degree of interest. Admirable as our public school system in many respects is, it undoubtedly demands an improvement in the proper grading of pupils of defective intelli-

gence. Public opinion, and especially public medical opinion, in this, as in many other matters, would do much to assist those in authority in carrying out what must be a difficult plan, even under the most favorable auspices. We beg to direct attention, therefore, to this report as a clear presentation of the difficulties which our public schools have to face and the ideals toward which they should strive.

CREMATION IN ENGLAND.

THE demand for facilities for the incineration of dead bodies has considerably increased in England in recent years. About 2,500 bodies have been incinerated at the Woking Crematory near London, and other establishments of similar character have now been erected at Manchester, Liverpool, Glasgow, Darlington, Hull and Leicester. This fact has given rise to a parliamentary inquiry upon the subject of cremation, which has now been made public.¹

The object of the investigation was to obtain the necessary information in order to prepare a draft of regulations required by the seventh section of the Cremation Act of 1902, which reads as follows:

"The Secretary of State shall make regulations as to the maintenance and inspection of crematoria, and prescribing in what cases and under what conditions the burning of any human remains may take place, and directing the disposition or the interment of the ashes, and prescribing the forms of the notices, certificates and declarations to be given or made before any such burning is permitted to take place, such declarations to be made under and by virtue of the Statutory Declarations Act, 1835, and also regulations as to the registration of such burnings as have taken place."—*Cremation Act, 1902* (2 Edward VII, Chap. 8, Sect. 7).

The principal persons who appeared before the committee were Sir Henry Thompson and the principal managers of different crematories, together with Dr. Stevenson, analyst to the Home Office. Sir Francis Seymour Haden, a prominent advocate of reform in earth burial, was the principal opponent.

One of the principal points in the inquiry was the alleged danger of employing cremation to destroy the evidence of crime. It appeared from evidence presented that cases had occurred in England in which the bodies of murdered persons had been buried without any certificate of the cause of death. It was also stated that the English law "permits burial without certification of the cause of death," and moreover that in "more numerous cases the certificate had been given without sufficient inquiry, sometimes by a medical man who had not

seen the deceased in his last illness nor the body after death. When Mary Ann Cotton, who for the sake of insurance money murdered no less than twenty persons in all, had disposed of a husband and four children in quick succession by arsenic poisoning, a medical man certified the deaths to be due to 'gastric fever,' although the symptoms were inconsistent with death from that cause."

With such facts in view the committee concludes that "the process of cremation must be carefully guarded," and that "regulations can be framed which will so far reduce the risk as to make cremation at least as safe as the existing method of burial."

With reference to such regulations, the first question considered was, "Who is to decide in each case whether a cremation is to be allowed?" It was suggested that either the medical officers of health or the coroners should perform this duty, and the chief coroner of London appeared in behalf of that body of officials. But the notoriously clumsy methods of the English Inquest Law were sufficient to defeat such reference in the opinion of the committee, and they finally decided to recommend the appointment of "medical referees specially qualified for the work." Fortunately, in Massachusetts, the introduction of improved inquest laws has furnished an intelligent body of officials to whom this duty has very properly been entrusted.

The second question to be considered was, "Whether the medical referee ought in every case personally to investigate the cause of death in such a way as to enable him to arrive at an independent conclusion on facts ascertained by himself, or ought merely to examine the medical certificates to see that they are satisfactory." To this inquiry the committee replied, "We have therefore come to the conclusion that before cremation is permitted, there must be in every case a personal inquiry by some one besides the medical attendant of the deceased."

More specifically the committee recommends that there should be required either (a) two certificates, one given by the medical attendant, the other by an independent person,—the medical referee, or a doctor nominated by the cremation authority, or a medical man holding some public responsible position—several of which are suggested in the report; or (b) a certificate given after a postmortem by a pathologist named by the cremation authority, who may or may not be the medical referee; or (c) a certificate by a coroner given after an inquest.

This investigation brought out some interesting facts in regard to the subject of exhumation for medico-legal purposes. It appears that in England, since 1893, annual returns are required from the coroners with reference to exhumations conducted

¹ Report of the Departmental Committee appointed to prepare a draft of the regulations to be made under the Cremation Act of 1902. Presented to both houses of Parliament by command of his Majesty, London, 1903.

under their orders. Hence the committee considered the question, "Whether the proposed regulations would be effective in cases where exhumation now takes place?"

During the nine years 1893-1901 the coroners had reported 95 cases of exhumation. Of these 67 had been ordered by coroners and 28 by the Secretary of State. So far, however, as the detection and punishment of serious crime is concerned, the result of all these exhumations in nine years in a population of over thirty millions is three convictions for murder, and one with a sentence of imprisonment for manslaughter. It seems clear, therefore, in the language of the committee, "that in these few cases where exhumation led to conviction and sentence for serious crime, the cremation of the body would have been impossible under the draft regulations, and that an application for cremation might possibly have resulted in the earlier detection of the crime. Further, as regards the more numerous cases mentioned, where exhumation led to no definite result, it is probable that, if in any of them application for cremation had been made under these proposed regulations, the inquiries which would have been made before the body had begun to decompose, and while the facts were still fresh in the memories of those concerned, might have resulted in the discovery of the cause of death, and, if there had been foul play, in the detection of the criminal."

The proposed regulations deal with the following subjects:

- (1) The maintenance and inspection of crematories.
- (2) The cases in which and conditions under which cremations may take place.
- (3) The disposition of the ashes after cremation.
- (4) The registration of cremations.

These proposed regulations are very fully and carefully drawn, and appear to cover every possible emergency, even to the cremation of the remains of still-born infants.

The appendices contain much interesting material, including the proposed blank forms, the regulations of existing crematories in England, and the laws of foreign countries upon this subject, including those of Massachusetts, the District of Columbia and the city of St. Louis.

THE PUBLIC HEALTH.

It would seem that information in regard to the life history of the typhoid bacillus is so complete, and so much a matter of common knowledge, as to make it doubly reprehensible that in an important educational center one of the worst of the recent

easily preventable epidemics should have taken place. It is reasonable to hope that a few additional communities, still negligent of the behest of the sanitarian, may profit to the extent of closing the door before, rather than after the loot of death. There are others, however, who will complacently say to themselves, we are secure, our water is filtered and pronounced safe by competent authority, we need fear no similar lesson of retribution. Such, indeed, may prove to be the fact, but even so they are not released from further effort. What of their ice supply? what of their milk supply? what of the care with which disinfection of excreta is practised in the sporadic cases, which competent authority says still impose a mortality tax of twenty-five deaths per 100,000 population in thickly settled communities?

Preventive medicine not only calls to her aid the pathologist, the bacteriologist, the epidemiologist, and the sanitarian, for instruction in the establishment of the rules of health and proper living, but she must rely upon the legislative body for laws embodying the principles of such of these rules as may be properly considered to affect the public health, and upon boards of health, both general and local, for supervision and enforcement of such laws, while assuming that the eventual details of personal hygiene will be scrutinized by the practitioner and attended to by the individual. Here is a chain whose weakest link may be easily parted, and it is a safe assumption that no community should flatter itself that all its links will stand the test. One spends millions for a new reservoir and protection of a water shed, and is content to let its citizens drink milk forty-eight hours from the cow, after twenty-four hours' storage in stable or shed, suiting the convenience of distributor or whim of housekeeper for early morning delivery; another insists on pure milk, and drinks water from grossly polluted wells; another coolly consumes its allotted pathogens served with salad or shellfish. A fond mother loudly protests against the neighbor's children who have whooping cough looking out of the window at her own, whom she hopes to keep germ free, while by the modish frills of her trailing skirt are entangled and diffused the mingled sweepings of a dozen streets. Vast sums are devoted to supplying "out door air" to discourage the growth of the tubercle bacilli already planted in the lungs of the indigent, while other sums collectively vast are spent to preserve in the homes of the well-to-do an atmosphere which, for temperature and humidity, is wonderfully adapted for favoring disease.

Community of interest, passing unrecognized, fails to arouse community of action. If a link fails the main chain for protection breaks; lateral chains

may or may not avail to hold the gate through which disease would enter. Where the most determined attack is made on the greatest common factor of disease, we may hope to find the least common multiple of annual deaths.

MEDICAL NOTES.

A CENTENARIAN. — It is reported that John Kehoe, who was probably the oldest person in Boston, died recently at the age of one hundred and five years.

THE FIRST BRITISH ARMY SURGEONS. — The first mention of surgeons in the British army is said to be found in 1223. There was a paid surgeon in the army of Edward I, which invaded Scotland in 1296.

A CENTENARIAN PHYSICIAN. — It is said that Dr. David of Montpelier, France, who recently celebrated his one hundred and second birthday, is the oldest living member of the medical profession. He practiced medicine till his ninety-eighth year, and is still in good health.

SANITATION OF CUBA. — According to the monthly report of Dr. Carlos J. Finlay, chief sanitary officer of the island of Cuba, it appears that Havana, as well as the rest of the island, has remained free from cases of yellow fever or smallpox originating within its territory. Precautions have been taken with regard to the introduction of bubonic plague, and for the purpose of disinfecting any suspected persons or vessels that may reach the island from infected ports. The sanitary department of Havana has continued the cleaning of houses and particularly the disinfection of tenements occupied by Chinamen. Somewhat drastic measures have at times been enforced to carry out the requirements of sanitation, but it is held that the end justifies the means taken.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, March 25, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 27, scarlatina 37, typhoid fever 7, measles 19, smallpox 1.

EXTENSION OF WORK OF TUFTS COLLEGE DENTAL SCHOOL. — It is announced that Tufts College proposes to extend the charitable work of the dental department, and for this purpose is desirous of securing a fund of \$100,000, the interest of which is thought to be sufficient to carry out the proposed plan.

THE INDEX MEDICUS. — The publication of the first number of the *Index Medicus* has been delayed by some unexpected difficulty with regard to the printing. It is to be remembered that although the Carnegie Institute has undertaken to support the *Index Medicus*, it is obviously desirable that a liberal subscription on the part of medical libraries and of physicians at large should give the managers of the Carnegie Institute a positive and practical assurance that this publication is really valued by the profession.

NEW YORK.

ORTHOPEDIC APPOINTMENT. — Dr. Frederick Mueller, recently assistant to Prof. Adolf Lorenz, and who accompanied the latter on his visit to America, arrived in New York from Europe on March 12, on his way to Chicago, where it is understood that he has been selected to fill the chair of orthopedic surgery in the medical school of the University of Chicago.

LEGAL APPLICATION OF BOARD OF HEALTH RECORDS. — By statute, where boards of health are required to register births, marriages and deaths, including causes of death, the record of these is *prima facie* evidence of the facts. But such records, the Court of Appeals holds, in the case of an administrator of an estate against the Metropolitan Life Insurance Company, are not evidence in an action upon a life policy to prove that the mother of the insured had died of pulmonary tuberculosis, and to impeach statements in that respect made in the application for insurance. In the opinion of the court the statute is a police regulation required for public purposes, and becomes *prima facie* evidence only so far as questions may arise under its provisions involving public rights. But, the court believes, it was not the intention of the Legislature to change the common-law rule of evidence in controversies of private parties growing out of contract, and the provisions of the statute should not, therefore, be construed as applicable to such cases.

TEACHING OF HYGIENE IN SCHOOLS. — In the course of a public lecture on "Tuberculosis and Children," delivered on March 16, by Dr. A. Jacobi, under the auspices of the Committee on the Prevention of Tuberculosis of the Charity Organization Society, he took occasion to criticise severely the extensive use of alcohol as a subject for hygienic teaching in the New York public schools. "What rot," he said, "the children are getting from the textbooks our taxes pay for, instead of the simple rules they ought to learn! Our schools are at the mercy of Mrs. Mary H. Hemtison of the Woman's Christian Temperance Union and of Eddyism."

HUDSON RIVER ICE POLLUTED. — On March 11 Dr. Daniel Lewis, state commissioner of health, appeared before the Senate committee on public health to urge the passage of the McCabe Bill, now pending in the Legislature, prohibiting the cutting of ice for domestic use on the Hudson River, between Waterford on the north and Coxsackie on the south, or within 3,000 feet below any town of more than 10,000 inhabitants on the river. At the same hearing Gen. Robert Avery of New York said that ice polluted by eighty sewers was sold for domestic purposes in New York City, and was frequently the cause of typhoid fever and other diseases. In the section of the Hudson excluded in the bill are the cities of Troy and Albany, and the mouth of the Mohawk River, on the banks of which many large towns are located.

A CENTENARIAN. — Mrs. Mary Johnson recently died in the almshouse on Blackwell's Island, at the reputed age of one hundred and five years. She was born in Ireland and was highly educated. Her husband was a civil engineer, and it is said that at one time she was well known in New York society.

A DEATH FROM HYDROPHOBIA. — Henry Stimson Loomis, the eight-year-old son of Dr. Henry P. Loomis, who was also a nephew of Dr. Lewis H. Stimson, died of hydrophobia on March 14. Six weeks previously his fox terrier was bitten by a large black poodle running loose on Fifth Avenue. Three weeks afterwards the terrier, without warning, bit the boy severely on the face, and slightly scratched his little sister. The animal was given into the care of the health department, and shortly afterwards died with all the symptoms of rabies, while inoculations with cultures from its spinal cord proved fatal to rabbits. Anti-rabic inoculations were immediately begun on young Loomis, but the infection which he had received seems to have been of unusual virulence, and on March 13 he was attacked with convulsions.

THE STRAINED RELATIONS AT ITHACA. — Renewed evidence of the strained relations which have existed during the typhoid epidemic at Ithaca between the faculty of the Cornell Medical School and the University Board of Trustees was furnished during the past week, when it was announced that Dr. Luzerne Colville had tendered his resignation, and that his resignation was immediately accepted. Dr. Colville, who has been lecturer on surgery in the medical staff of instruction in Ithaca, took a prominent part in the organization of the medical department of the university, and was appointed the first secretary of the medical faculty at Ithaca. His resignation is said to be on account of expressed differences between himself and the infirm-

ary committee of the trustees concerning the management of the infirmary. It is also stated that Dr. A. T. Kerr, the present secretary of the faculty and also assistant professor of anatomy, was made a member of the infirmary committee while the epidemic was at its height, but after serving forty-eight hours gave up the position; since which time no representative of the medical profession has been on the committee. As a result of his investigation of the conditions existing at the infirmary he made certain suggestions, and as the committee declined to carry them out, he felt compelled to withdraw. A death from typhoid fever in a Cornell student occurred at Utica, N. Y., on March 19.

A CASE OF GLANDERS. — Benjamin Hilson, fifty-two years of age, died recently at the Metropolitan Hospital on Blackwell's Island from glanders, and the autopsy in the case was made on March 20, by Dr. A. T. Weston of the coroner's office, in the presence of a number of interested physicians and surgeons. Hilson was an employee in a cigar factory on the East River, on the ground floor of the building next to which there is a horse market, and it is supposed that in this market he received the glanders infection in an injured finger.

A SAMUEL THOMAS MEMORIAL WARD. — At a meeting of the directors of the Manhattan Eye, Ear and Throat Hospital held March 17, it was announced that the widow and children of the late Gen. Samuel Thomas have made a gift of \$50,000 for the endowment of a ward with ten beds, to be called the Samuel Thomas Memorial Ward, in the new building which it is proposed to erect for the hospital. One hundred thousand dollars of the \$200,000 required for the building has now been subscribed.

DECISION ON THE DISTRIBUTION OF MILK. — On March 19 the Appellate Division of the New York Supreme Court rendered a decision to the effect that the section of the Sanitary Code which provides that "no milk shall be received, held, kept, offered for sale or delivery in the city of New York without a permit in writing from the Board of Health, and subject to the conditions thereof," is constitutional and valid under the police power of the State. In the case at issue, the main contention was that it was apparent on the face of the ordinance that it is unreasonable and void in that it makes it unlawful for hotels or even private consumers to have milk in their possession without a permit. Justice Laughlin, for the court, holds that the ordinance is susceptible of the construction that it is intended as a regulation of those offering milk for sale, rather than of consumers and can be held valid in that respect.

Correspondence.

LETTER FROM THE PHILIPPINES.

FROM OUR SPECIAL CORRESPONDENT.

THE CHOLERA EPIDEMIC — BUBONIC PLAGUE — SMALL-POX — A HILL SANITARIUM.

MANILA, Feb. 10, 1903.

At the present time, cholera is markedly abating in the Philippine Islands, though still very severe among the Mora natives of the Sulu group and the island of Mindanas. It has ceased as an epidemic on the island of Luzon, though cases keep cropping up throughout the provinces, showing the continued widespread existence of the infection. Should this infection survive until the beginning of the rains, as now seems highly probable will be the case, another epidemic, spread from existing foci under more favorable meteorological conditions, may be expected during the present year. No cases of cholera have occurred in Manila during the past fortnight, and but few since the beginning of the year. The quarantine of outgoing vessels sailing from Manila has been provisionally suspended for this reason, and also because most of the other islands of the archipelago are now, or have been, infected with cholera. Vessels sailing for the United States will not be subjected to quarantine unless passengers are from the badly infected parts of the southern islands, and have not completed five days since their departure from such places; but passengers will be inspected by the quarantine officers before a bill of health is granted. The cholera situation in the province of Albay, in the southern part of Luzon, looked very serious several weeks ago, but favorable meteorological conditions and energetic action by the health officials seem to have brought the epidemic under full control. Among the Moras of the southern islands, who are largely unfriendly, nothing can, of course, be done to stay the disease, but the epidemic appears to be gradually dying out from natural causes. So far, more than 80,000 deaths from cholera have been reported to the health authorities since the beginning of the epidemic, ten months ago; and these figures probably represent but little more than half the actual mortality from this cause, since in many cases the cause of death was concealed, or there was no sanitary organization through which the true state of affairs could be reported to the health authorities. A fair numerical estimate of the havoc which cholera has wrought in these islands would be placed at 160,000 deaths and 250,000 cases. How much these figures are to be increased during the present year it is, of course, impossible to say.

Looking back over the epidemic of the past ten months, one is impressed by the fact of the absolute hopelessness of maintaining an effective quarantine in these islands, either by land or sea, with the Filipino nature as it is. It has been necessary to not only fight the disease itself, but to come into constant conflict with the ignorance, superstition, fatalism and habits of life of the natives, for whose protection the sanitary work was being done. Not a regulation was made which the natives did not seem to take delight in disobeying if this could be done without punishment, and punishment for doing the unsanitary things which they and their ancestors had done all their lives merely created irritation and provoked resentment. To their way of thinking, all Americans were to be distrusted, and sanitary improvements were fraught with something harmful to the natives, even though outwardly for their benefit. Disease and pestilence were sent by a displeased heaven, and human efforts to avert them were not only futile but impious. Americans were thought guilty of spreading the cholera through the poisoning of wells — an idea favored by the free use of disinfectants where the disease was at its worst. Invocations to the saints were regarded as more efficacious than the use of boiled water, and charms and amulets as better protections against the disease than quarantine. Isolation of the sick was regarded as unnecessary, and cremation of the dead as revolting to religious ideas. With such beliefs firmly implanted in the Malay mind, the wonder is that so much good has been accomplished

and that the Filipinos have been saved from themselves, in spite of themselves, to such an extent.

A second point is that cholera is a disease readily amenable to control, if proper measures of prevention are carried out. This is particularly well illustrated in the case of troops, which in many instances have been kept free from the disease while the surrounding native population was being more than decimated. Where the cholera occurred among soldiers, its origin could almost invariably be traced to some flagrant violation of sanitary orders. In the few instances where the disease did fail to prevail to a considerable extent, the application of strict measures of quarantine, isolation, disinfection and the sterilization of food and drink, promptly brought the threatened epidemic to a close. Such well-marked examples of the protection afforded by this means were so frequent that it is scarcely too much to say that the cases which did occur among the troops were not only unnecessary but were a reflection upon the discipline of the command and the sanitary condition of the post. With boards of health clothed with ample powers, and with an intelligent civil population willing to co-operate in the execution of sanitary measures, the importation of cholera infection into a civilized community should be stripped of most of its terrors. There are always a few persons in even the best-ordered communities who, from ignorance, indifference or wilfulness, will not do as they are told. This class is invariably attacked by cholera in the presence of an epidemic, and their demise is scarcely to the material injury of the community at large. The proportion of the irresponsible, worthless and vicious element of Americans who fell victims to cholera in Manila was very noticeable.

Another feature of the recent epidemic was its self-limited character. The disease would attack a hitherto uninfected district with great violence, a large number of cases would occur, and most of the individuals attacked would promptly die. As time went on, fewer persons would develop the disease, its course would be more protracted, and a gradually increasing proportion of cases would recover. Finally, the disease would die out, or the infection become quiescent, apparently more from an attenuation of the virulence of the germ than the lack of susceptible material — and more or less irrespective of such sanitary measures as were instituted. In its course the epidemic resembled that of a prairie fire, raging along the advance line, and leaving in its wake a space on which no more damage seems to be possible.

It was also demonstrated that no small proportion of the native population presented a natural immunity to the disease. Native conditions of life are such that where one member of the household contracted the disease the others were very probably exposed to infection from the same source; and in small villages deriving a common water supply from the same well, which was early infected, it is scarcely probable that any of the villagers escaped taking infectious material into the system. In spite of this, even in the worst infected places, from 25 to 35% of the population seemed to possess a complete resistance against the disease, although this relative immunity varied with the place and season, and presumably with the virulence of the specific micro-organisms.

The disease spread along the lines of travel, and, in the country districts, at the rate of ten or twelve miles daily, or about as much as a native and his bull cart could average as a fair day's journey. After it had gained entrance to a district, it was usually transmitted by means of water, through the use of infected foods, the unsanitary habits of the natives, and the transmission of the infection by personal contact played no small part in the dissemination of the disease.

Direct infection from the sick has been relatively rare, particularly so if the simplest precautions were taken for protection. In the cholera hospitals in Manila, with the hundreds of cases treated, scarcely a case occurred among the attendants, many of whom were natives and who probably did not fully carry out all sanitary precautions. Where several cases occurred in native families, those developed later seemed to spring from the original source of infection rather than direct contact with the sick. A certain number of cases from contact undoubtedly occurred, but they were by no means as many as it had been expected would occur.

An interesting feature of the cholera outbreak in Manila was its occurrence in Bilibid Prison, where about two thousand prisoners were confined, in spite of all precautions to prevent its entrance. These precautions included the use of boiled water, the non-use of uncooked food, the prohibition of any gifts being received by prisoners or their seeing visitors from outside, and the isolation of all new prisoners for five days before they were allowed to mix with the others. The first case of cholera appeared early in the epidemic in the city in the person of a prisoner who had been confined two days previously. Two days later the disease developed in a native, who occupied a room next to the one in which the first case appeared, and five days later it attacked a Chinaman in the main prison. No new cases appeared for about a month, and then three cases occurred in the same building, at intervals of three days. The two last cases were probably contacts. There were no more cases for six weeks, when the supply of distilled and boiled water failed, and the authorities of the prison allowed the prisoners to use hydrant water. About a week later a case of cholera appeared, and nine more cases developed at short intervals during the next fortnight. There was no apparent connection between any of these cases, as they appeared in different buildings, in different parts of the prison. Careful investigation showed that apparently the water was the sole agent by which the infection was conveyed within the prison walls. There was some delay in putting in distilling apparatus, and during the month twenty-three cases occurred. The day after the distilling plant started up one case developed, but no more appeared for several months; then six cases appeared in prisoners who were found to have used the bath water for drinking purposes. This epidemic in Bilibid Prison is important in that it gives much evidence to show that the Manila water supply was infected, a thing which was not supposed by the health authorities to have occurred. Careful examination of the water supply was continually made and checked by several observers, but the presence of the cholera spirillum was never detected. It was also argued that if the general water supply was infected, the epidemic would have been much more serious and widespread in Manila than it proved to be. It was known, however, that cases of cholera occurred in the watershed from which the city supply is drawn, and it was fair to presume that cholera discharges found their way into this supply. The water supply of Manila is insufficient, however, and during the cholera was very frequently drawn from the rapidly flowing Mariquina River and pumped directly to the city, without storage, where it was at once used up. Hence infections were liable to be only temporary and not continuous, as would have been the case had the sluggish waters of a large reservoir been contaminated.

Under the former conditions it is possible to conceive that the Manila water supply might have been infected for short periods from time to time, without any resulting permanent infection, the streams being cleared of infection by frequent flushing from the torrential rains. It may be, also, that the joints of some of the branches of the pipe may have been opened by earthquakes or accident when they passed through sewage polluted ground, and that cholera discharges in this way gained access, from time to time, to certain parts of the water system. That there occurred a general and continuous infection of the water supply, such as existed in the Hamburg outbreak of 1892, there is no reason to believe; else the number of cases which should have occurred in Manila would have been ten times the 4,000 which actually appeared. The epidemic would have been fulminant in type, and a large number of cases would have developed in a short period, with a persistently infected water supply. This fact was shown in outbreaks on the island of Panay and elsewhere, where a fourth of the population of large towns contracted the disease. Had the same conditions obtained in Manila, with its large population, it is fair to presume that from seventy-five to a hundred thousand cases of cholera would have occurred.

Bubonic plague still maintains a foothold in Manila, although but few cases occur. New cases develop from time to time with considerable regularity, and the infection does not seem to be strictly limited to any particular

section of the city, though the majority of cases occur in the Chinese districts and those inhabited by the poorer class of natives. Practically all those attacked by the disease die promptly. The health officers maintain a number of gangs of rat catchers, who are constantly at work, and the number of plague rats has been growing less and less until now they have practically disappeared. The work of rat-catching is still kept up as a precaution, however, and every effort is being made to improve the sanitary condition of the poorer districts.

Owing to the outbreak of smallpox at several points in the provinces, the Board of Health has decided that every person in Manila must be vaccinated. The number of vaccinators has been added to, and it is expected that the work will be completed in the course of the next two months. Several sharp outbreaks have occurred on the islands of Samar, Luzon and Leyte, and wholesale vaccinations are in progress on those islands. In the last six weeks, 210,000 units of vaccine virus have been sent out from the government laboratories, 150,000 of which were used for vaccinations in Manila alone.

The sanitarium idea developed by the British in the establishment of their "hill stations" in India is being followed by the authorities in the Philippines in their creation of a sanitarium and resort in the mountains at Bagnio, Bengnet Province, and the practical removal of the seat of the insular government to that place, during the rainy season in Manila, which is expected to be inaugurated during the present year. A sanitarium was projected in Bengnet Province by the Spanish authorities, but the plan was never carried out. The site selected, and upon which a sanitarium, hotel, etc., is now being constructed, and near which the military authorities have reserved a tract of land for an army station, is located in the northern part of Luzon and about forty miles from San Fernando de Union, the nearest seaport. The great drawback to the site is its inaccessibility, as a large part of the trip must be made on litters carried by Igorrotes or on horseback, and the trail is so difficult from San Fernando as to make it necessary to spend three days in accomplishing the forty-mile journey from that station. The government is now spending \$200,000 on a good wagon road to run through Pozorubio to connect with the Manila and Dagapan Railway, and good access to Bagnio should be had within four or five months. It will mean much to the Philippines to bring Manila into ready communication with the new sanitarium, since the sick and those broken down by overwork or the climate are now forced to leave the islands and go to Japan or the United States to recuperate.

The mountains of Bengnet are very high and rugged, and are covered with pines above the altitude of about four thousand feet. The air is very cool and bracing, and the climate very similar to the tablelands of Arizona, except for the greater dryness of the air of the latter. There are many deep canons containing rushing mountain streams of clear water, and the pine forest is broken here and there by grassy parks. The soil consists principally of a reddish clay, black loam, conglomerates and limestone. While the climate is as cool, invigorating and favorable to the sick as that of the tablelands of Colorado, Arizona and New Mexico, it can never be regarded as favorable for lung troubles because of the humidity. Observations taken by the Spaniards place the mean maximum temperature at 73° F., while the thermometer often falls to 42° or 43° F. just before daybreak. The mean humidity reported by the Spanish commission was 62.25, the highest 72 and the lowest 52, taken during the months of November, December, January and February. During the summer months the percentage of humidity is less. A fog usually drifts in from the China Sea about evening, and fires are required for comfort. Mosquitoes are few in number, and the region appears to be free from malaria. There are a number of thermo-medical springs in the vicinity. The country in the vicinity is known to produce many of the fruits and vegetables grown in the temperate zone, and there would seem to be no reason why the others should not grow there. The new sanitarium would seem to be well adapted for the recuperation of cases of general debility, anemia, malarial cachexia, diarrheas and dysentery, and as a summer home for the Americans, especially the women and children, living in the islands.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MARCH 14, 1903.

| CITIES. | Population Estimated, 1903. | Reported deaths in each. | Deaths under five years. | Percentage of deaths from | | | | | |
|--------------|-----------------------------|--------------------------|--------------------------|---------------------------|----------------------|-----------------------|-----------------|----------------|--|
| | | | | Infectious diseases. | Acute lung diseases. | Diphtheria and croup. | Whooping cough. | Scarlet fever. | |

| Plymouth | 11,077 | 3 | — | — | — | — | — | — | |
| | 10,730 | — | — | — | — | — | — | — | |

Deaths reported, 3,919; under five years of age, 1,023; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 875, acute lung diseases 799, consumption 431, scarlet fever 37, whooping cough 42, cerebrospinal meningitis 13, smallpox 9, erysipelas 9, measles 39, typhoid fever 82, diarrheal diseases 72, diphtheria and croup 86.

From whooping cough, New York 7, Chicago 10, Philadelphia 3, Pittsburg 10, Providence 1, Boston 5, Lynn 3, and Cambridge, Somerville and Chelsea 1 each. From erysipelas, Chicago 2, Philadelphia 5, Baltimore 1, Springfield 1. From smallpox, Chicago 2, Philadelphia 5, Pittsburg 2.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending Feb. 28, the death-rate was 16.6. Deaths reported, 4,789; acute diseases of the respiratory organs (London) 271, whooping cough 108, diphtheria 81, measles 104, smallpox 17, scarlet fever 52.

The death-rate ranged from 8.2 in Hantsworth to 24.3 in Wigan; London, 16.3, Westham 16.1, Brighton, 15.8, Portsmouth 13.9, Southampton 14.7, Plymouth 20.5, Bristol 15.8, Birmingham 20.1, Leicester 18.0, Nottingham 17.6, Bolton 12.6, Manchester 20.9, Salford 23.0, Bradford 13.8, Leeds 15.6, Hull 15.0, Newcastle-on-Tyne 16.9, Cardiff 16.3, Rhondda 16.1, Liverpool 20.7, Burton-on-Trent 17.2, Kings Norton 9.8, Great Yarmouth 17.1.

METEOROLOGICAL RECORD.

For the week ending March 14, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

| DATE | Bar- om- eter. | Ther- mometer. | | Relative humidity. | | Direction of wind. | | Velocity of wind. | | We'th'r * | | Rainfall in inches. | | |

CHANGES IN THE MEDICAL CORPS OF THE NAVY, FOR THE WEEK ENDING MARCH 21, 1903.

A. W. KAINES, acting assistant surgeon. Appointment revoked to take effect upon reporting of relief.

F. L. BENTON, passed assistant surgeon. Ordered to the Naval Station, Cavite, P. I.

G. A. LUNG, surgeon. Detached from the Bureau of Medicine and Surgery, and ordered to the Naval Hospital, Philadelphia, Pa.

J. STEPP, assistant surgeon. Detached from the Isla de Luzon and ordered home to wait orders.

P. L. COCKE, acting assistant surgeon. Ordered to the Naval Academy, Annapolis, Md.

F. A. HESLER, surgeon, died March 11 on board U. S. S. "Wilmington," en route from Cavite, P. I., to Yokohama, Japan.

SOCIETY NOTICE.

ANNUAL MEETING OF THE AMERICAN UROLOGICAL ASSOCIATION.—The annual meeting of this association will be held the last day of the American Medical Association's meeting and the day following, at New Orleans, May 8 and 9.

FERD. C. VALENTINE, M.D.
Secretary.

RECENT DEATHS.

BENJAMIN MILLER VAN SICKLE, M.D., a graduate of Rutgers College and Bellevue Hospital Medical College, and for several years a practicing physician in New York, died at his mother's residence in Newark, N. J., on March 15, at the age of forty-six.

GEORGE BEERS, M.D., of New York died from pneumonia on March 16, in the thirty-fourth year of his age. He was born in New York and was graduated from the College of Physicians and Surgeons in that city.

J. L. CILLEY, M.D., of Brooklyn, N. Y., died on March 18. He was born in Cincinnati on Jan. 25, 1838, and was a graduate of Harvard University and the Miami Medical College in Cincinnati. He was for nineteen years demonstrator of anatomy in the Ohio Medical College and also occupied for some time the position of professor of anatomy at the Cincinnati Art Academy. During the Civil War he served in both the army and the navy. He went to New York eighteen months ago, and soon became favorably known among the artists of the city through his lectures on "Anatomy for Artists."

Address.

THE CLINICAL SIGNIFICANCE OF ARTERIOSCLEROSIS.¹

BY REGINALD H. FITZ, M.D.

For many years the anatomical changes so frequently found in the aorta of persons beyond middle life and included under the term arteriosclerosis or endaortitis deformans were considered by practitioners of medicine as of relatively little importance.

They so frequently were independent of any disturbance of function attributable to their presence that they were regarded rather as senile changes of comparatively little significance than as manifestations of disease. They could not be regarded even as evidence of senility, since not infrequently they were absent in the arteries of persons of extreme old age and occasionally were to be encountered in those of children.

It has long been recognized that the larger arteries of the brain, heart, kidneys, spleen and extremities might show alterations somewhat similar to those occurring in the aorta and its largest branches, and that pathological processes in the organs concerned might be associated.

It is only within comparatively recent years, however, that more searching attention has been directed by the pathologist to the lesions of the minuter arteries of the viscera and to their effects. As a result of these investigations the possibility of the existence of a disease, arteriosclerosis has received general recognition.

But the pathologist has found it difficult to identify the lesions of the larger arteries, notably of the aorta, with those occurring in the small arteries, especially of the viscera. The growth of tissue, the modifications of caliber, the presence of fat, the deposition of earthy salts, were readily found in arteries investigated with the scalpel and scissors; they also could be determined in arteries whose physical characteristics became apparent only with the aid of the microscope. Whether rightly or wrongly it has become the custom to identify these changes in the larger and smaller vessels under the general term arteriosclerosis, and to discriminate between the nodular arteriosclerosis of the larger vessels and the diffused arteriosclerosis of the smaller arteries. It is to be questioned, however, to what extent these affections of arteries of large and small caliber are identical.

A traumatic, syphilitic or tubercular endarteritis is manifested in minute arteries by sclerotic changes quite distinct from those of chronic endaortitis deformans; and the latter process may be present in syphilitic or tubercular patients long before either syphilis or tuberculosis has been acquired.

The difficulty experienced by the pathologist in unifying the various anatomical changes found in arteries of large and small caliber makes it necessary for the practitioner to be especially cautious in generalizing with regard to the clinical manifestations of arterial disease. It is important for him to weigh carefully the evidence in the individual

case, that he may attach the proper value to it in determining questions of diagnosis and treatment.

The disturbances produced by arteriosclerosis are dependent essentially upon the resulting modifications of caliber and the alterations of surface in the arteries of the viscera and extremities. The changes of caliber are due chiefly to failing elasticity, however induced, or to obstruction from narrowing or twisting of the canal and to irregularities of surface. The ultimate result is a loss of nutrition, either slowly produced or suddenly brought about. The consequences are various disturbances of function which concern the organs especially affected, but which may be identical with disturbances of function otherwise produced.

The patient suffers from predominant affection of the brain, heart, kidneys or extremities, and it is desirable, therefore, that the organs especially concerned should be made most conspicuous in the diagnosis. It is important to recognize that he has an arteriosclerotic encephalitis, myocarditis or nephritis, since the prognosis may depend largely upon the discovery of arteriosclerotic basis for the lesions.

The treatment also of an arteriosclerotic nephritis, or of a nephritis with arteriosclerosis elsewhere, may demand the most urgent appreciation of the existence of the arteriosclerosis.

It would seem, therefore, of clinical convenience to consider arteriosclerosis as a morbid process which may affect the central, peripheral and visceral arteries of the body. Each group alone may be concerned, or two or more groups may share simultaneously in the process. Usually the effects of arteriosclerosis are more apparent in a single group, and in visceral arteriosclerosis the results are more conspicuous in one organ than another, although combined disturbances of several organs are frequent in consequence of various degrees of arteriosclerosis in each. Hence there is no typical picture of arteriosclerosis from a clinical point of view, but there are several diseases variously designated which may be attributable to arteriosclerosis. This term, therefore, to the clinician, represents rather a species than a genus, and strictly speaking should be used as an adjective, not as a substantive.

A diagnosis of the condition arteriosclerosis usually is made by the physical examination of the accessible arteries and of the heart.

The arteries are cordlike, resistant, tortuous, with a ribbed or granular surface. The tension of the pulse is high. The heart gives evidence of hypertrophy of one or both sides by an increased area of dullness, a more powerful apex beat and an accentuation of the second aortic sound, provided the aortic valve is sufficient.

Although the presence of a cordlike resistance is most significant of arteriosclerosis, it is not always found in arteriosclerosis of the internal organs, and when appreciable does not indicate that existing visceral disease is due to arteriosclerosis. Its importance as a characteristic sign is so great, however, that it always should be sought for, and the brachials, femorals and tibials as well as the radials should be palpated, since arteriosclerosis when present is not necessarily generalized but may be

¹ Extract from an address before the Hampden Medical Society at Springfield, Oct. 21, 1902.

confined to or be more conspicuous in certain vascular territories.

The significance of tortuous arteries in the diagnosis of arteriosclerosis often is overrated.

Indeed, it is by no means certain that the process which causes serpentine arteries is that which produces thickening and rigidity of the arterial wall. Although in generalized arteriosclerosis the visible arteries often are tortuous, visceral arteriosclerosis frequently is unaccompanied by tortuous temporal or brachial arteries.

Serpentine temporal arteries repeatedly are seen in youths and young men who at the time or in after life are not to be regarded as sufferers from arteriosclerosis.

The ribbed or granular condition of the surface of an artery is due to calcification, but the question still is unsettled whether or not calcification of the peripheral arteries is necessary evidence of arteriosclerosis in them. Certainly peripheral calcification, even of tortuous arteries, may be present without thickening of the walls or evidence of visceral arteriosclerosis. Although calcified arteries are oftenest found in the aged, persons under middle life are not necessarily free from this evidence of degeneration.

The pulse of high tension usually excites the suspicion of arteriosclerosis, especially in the early stage. It is by no means pathognomonic, however, for it is not always present in arteriosclerosis; indeed, there may be lowered tension when there is even extensive arteriosclerosis, and in chronic nephritis without arteriosclerosis the tension of the pulse may be abnormally and persistently high.

In like manner hypertrophy of the heart, with or without a heaving impulse and accentuated second aortic sound, may be absent in arteriosclerosis, and when present may result from other conditions than this lesion. Such is notably the case in chronic nephritis, which may or may not be connected with arteriosclerosis.

The clinical importance of the recognition of the presence of arteriosclerosis demands not only the physical examination of accessible arteries and the heart, but also the use of such means as we may have of determining the condition of other organs whose arteries are especially liable to become sclerotic.

It is, therefore, convenient in the diagnosis of the possible arteriosclerotic nature of a given disease to bear in mind the previously mentioned topographical distribution of the arteries into central, peripheral and visceral groups.

In central arteriosclerosis, in which are affected the aorta and its larger primary branches, excepting those of the heart and kidneys, the diagnosis depends partly on an inference from age, and more particularly upon the physical examination of the branches within reach of the eye, ear and finger. Although most people over fifty years of age have more or less aortic arteriosclerosis, there are numerous exceptions, and occasionally persons of advanced years show a clean aorta, and youthful individuals may have one which is diseased.

Inspection and palpation of the innominate, subclavians, carotids, femorals, and, when possible, of the iliacs, may reveal the dilatation and rigidity which usually accompany aortic sclerosis, and a con-

current dilatation of the arch of the aorta may be determined by auscultation, percussion, and perhaps palpation of the area concerned.

When aortic arteriosclerosis involves the coronary and renal arteries the resulting disturbances of function are those of visceral arteriosclerosis, and when present in addition to the above-mentioned evidence indicate the extension of the process from the aorta to the arteries leading to the affected organs.

In peripheral arteriosclerosis the physical examination of the accessible arteries is the chief reason of diagnosis, although the evidence of an enfeebled circulation is usually furnished by the sense of discomfort,—even severe pain and numbness in the extremities, and by the rapidly induced fatigue and cramps in individual muscles or muscular groups.

The diagnosis of visceral arteriosclerosis depends first upon the recognition of the various disturbances of function and then upon the discovery of evidence of central or peripheral arteriosclerosis. Such evidence confirms the diagnosis, but does not prove its correctness, since other causes exist for the ascertained disturbance of function, and the evidence of central or peripheral arteriosclerosis does not necessarily indicate that the disturbed functions of the viscera are occasioned by sclerosis of its arteries. In visceral arteriosclerosis it is customary to recognize three principal types of disease—the cerebral, cardiac and renal. The intestinal and pancreatic types have more recently been added to the series. The three principal varieties alone are those which concern most practitioners.

The cerebral type is indicated by such disturbances of function as headache, vertigo, wakefulness, loss of memory, convulsions and focal lesions due to arterial rupture, thrombosis or embolism. In cardiac arteriosclerosis the final result is fibrous myocarditis with dilatation and insufficiency, or death may occur suddenly from rupture of the heart in consequence of coronary thrombosis or embolism. The symptoms in general are those of a weak heart; and palpitation, bradycardia or tachycardia, arrhythmia, angina, dysprosia, cardiac asthma, Cheyne-Stokes breathing, epileptiform attacks, unconsciousness, and passive congestion of the various organs, and dropsy, are to be recognized.

In renal arteriosclerosis the signs and symptoms are those of chronic fibrous nephritis. Inasmuch as a peripheral arteriosclerosis may develop in the course of a chronic nephritis, and an arteriosclerosis of the kidney produce the manifestations of a chronic nephritis, the diagnosis of an arteriosclerosis nephritis is always a problem for the practitioner, and is more easily made after than before death.

The intestinal type of arteriosclerosis has aroused attention of late years from its significance in the causation of acute intestinal symptoms, simulating obstruction and suggestive of peritonitis. Thrombosis and embolism of the sclerotic arteries result in ulceration, perforation and necrosis, which rapidly assumes a gangrenous character.

In arteriosclerosis of the pancreas, as of the kidney, the question as to the effect of arteriosclerosis upon the pancreas or of the production of arteriosclerosis by disease of the pancreas is answered with difficulty. But the increasing importance of recognizing disease of the pancreas as an organic basis

for saccharine diabetes, and the knowledge that peripheral arteriosclerosis is of occasional occurrence in diabetes, and an important element in the causation of diabetic gangrene, suggests that arteriosclerosis may play an important part in the pathology of diabetes mellitus.

It is evident that in no instance of visceral arteriosclerosis is the diagnosis to be made from the knowledge of disturbance of function alone. The functional disturbances may be due to various causes, one of which is arteriosclerosis; and it is the association of this lesion in the central and peripheral vessels with the symptoms of such disturbed function in an organ which permits the diagnosis of a visceral arteriosclerosis.

The value in therapeutics of recognizing the existence of arteriosclerosis is chiefly in the way of caution. There are no remedies which can cause arteriosclerosis to disappear, and it is doubtful to what extent, if any, its progress can be arrested. Perhaps the chief benefit of the early discovery of arteriosclerosis comes from the opportunity it gives of warning the diseased person of the necessity of a change of habits, of avoiding mental, moral and physical strain upon blood vessels which already show signs of weakness. The dilated temporal arteries of youth are no necessary evidence of advancing arteriosclerosis; they are a sign to go slowly, to avoid excesses and unnecessary exposure.

CÆSARIAN SECTION FOR PLACENTA PREVIA, WITH REPORT OF A CASE.¹

BY P. E. TRUESDALE, M.D., FALL RIVER, MASS.,

Gynecologist and Obstetrician to Fall River City Hospital.

THE advent of Cæsarion section as a logical treatment for placenta previa has invited the severest criticism and the warmest approbation of different obstetricians throughout this and other countries.

Some have recommended it as the ideal treatment in all cases of placenta previa, while other authorities have tabooed it altogether.

It is much within the confines of these extreme views that we hope to gain for the Cæsarion operation a recognition which it already merits. We cannot expect to show by this treatment the low mortality attained by Reynolds, Schauta, Everke and Leopold, in their Cæsarions for contracted pelvis, because of the difference in manifestation of these two pathological conditions. A certain proportion of the patients with placenta previa will always continue to be presented for operation in emergency. When, however, every physician doing obstetrical work is made conscious of his duty to keep under closer observation his pregnant cases, the patients with critical hemorrhage, at or near full term, will be less common, and the results by the Cæsarion treatment more favorable for comparison.

During the past three years, and especially since the report of Donoghue's case¹ in 1900, treated successfully by Cæsarion section, there has been

produced a wealth of statistics from which can easily be taken statements in support of any method of treatment.

For a review of the mortality statistics, I refer you to an article by Hugo Ehrenfest² of St. Louis, published in *American Medicine*, Jan. 11, 1902. He quotes the individual results of thirty authors, and we find that there is an average maternal mortality of about 7%. The mortality of the fetus is not noted in any instance. He strongly opposes Cæsarion section for this complication of pregnancy.

To offset any prejudice that may be acquired from a study of his investigations, I refer you to another column of mortality statistics in a paper by E. Gustave Zinke,³ read before the American Association of Obstetricians and Gynecologists, Sept. 18, 1901. From thirty authors he finds an average maternal mortality of 25% and a fetal mortality of 65.21%. In his own cases there was a maternal mortality of 17.5% and fetal of 55%. He says: "I firmly believe that Cæsarion and the Porro operations are perfectly legitimate, and elective procedures in all cases of placenta previa, central and complete, and especially so when the patient is a primipara, when the os is closed and the cervix unabridged."

In justice to Ehrenfest, it should be said that the cases in his statistics were collected since 1898.

It is hoped that in the future reports of cases an analysis of the degree of previa will be given, also the mortality in each variety.

Of 234 cases of placenta previa reported by Schauta,⁴ 50 were complete. Of this number there was a maternal mortality of 18% and a fetal mortality of 70%.

Of 75 cases reported by Higgins⁵ from the records of the Boston Lying-in Hospital, 25 were of the complete variety. Of these six died, or 24%.

Jardine⁶ reports 12 complete previa, with a maternal mortality of 16 $\frac{2}{3}$ % and fetal mortality of 66 $\frac{2}{3}$ %.

Jewett's "Obstetrics," 1899, gives 739 collected cases, with 166 deaths, 109, or 14.7%, of which were complete.

Gillette,⁷ by direct correspondence with leading obstetricians at maternity institutions of this country, received reports of 216 cases of placenta previa. Of the 216, 88 were complete, and of this number 20 were lost, or 22.7%; 66 of the babies, or 70.5%.

F. A. Dorman⁸ reports 84 cases of previa treated at the Sloan Maternity Hospital; maternal mortality in all cases was 12%, fetal 45%. In a personal communication from Dr. Dorman he informs me that of the complete type there was a maternal mortality of 17.7%.

From the above statistics, we find in complete previa an average maternal mortality of 18.9% and a fetal mortality between 65 and 70%. These results were attained in maternity hospitals by expert obstetricians, and will probably never be much lowered by any vaginal method of treatment.

It is this high, though conservative estimate of the mortality in complete placenta previa that we aim to reduce by Cæsarion section.

In partial previa the maternal mortality by version probably does not exceed 5%. But in obtaining this low figure, half of the babies are sacrificed in delivery, by obstruction of the circulation through

¹ Read before the Obstetrical Society of Boston, Jan. 20, 1903.

the placenta and by slow extraction. If the life of the child is to receive a just consideration, then a method of treatment which will greatly reduce its mortality and involving little, if any more, risk to the mother should be accepted.

Hirst says: "The treatment ought to be such as will secure the least maternal and the least fetal mortality. While, of course, the life of the mother is the greater importance, yet it is a mistake to ignore all consideration of the life of the child."

Dr. Barnes has said: "It is no longer permitted to us, without ample proof of clear necessity, to sacrifice the child in order to save the mother. The cases in which the two lives are supposed to stand in antagonism are vanishing before the light of modern science and skill. And in no conjuncture is this more true than in the treatment of placenta previa."

Lateral insertion of itself does not justify a Cæsarian operation. As a rule, simply rupturing the membrane suffices to stop hemorrhage.

In the 84 cases reported by Dorman, the bleeding at the onset was moderate, and gradually increasing and independent of labor pains in 50%; in 10% it began moderately after the beginning of labor; in 40% there was a sudden profuse flooding; although in one third of these cases slight preceding attacks of bleeding had given warning signs. Then in about 27%, or that number in which there was no premonition at all, undoubtedly occurs the highest mortality. Dorman also states that over half of the women with complete previa went to full term. Of 128 deaths reported by Müller not one occurred before the seventh month, and one third reached the end of gestation. In the 34 deaths reported above by Gillette⁷ all occurred after the seventh month. Could not the diagnosis then be made by careful examination before the seventh month?

The period of greatest danger, then, is that during which the child is viable.

If as routine practice all pregnant women were examined each month after the fifth, this type appropriately called "vicious" would rarely escape recognition. Early diagnosis, removal of the patient to a well-appointed hospital and Cæsarian section performed during the last two weeks, or the last month of gestation, would, without doubt, result in an exceedingly low maternal and fetal mortality.

As gestation approaches term, the life of the child demands greater consideration.

R. P. Ranken Lyle,⁹ referring to vaginal treatment, says: "In most cases the best treatment for the mother is the worst for the child."

If the fetus is viable, should it be sacrificed by slow delivery to save the mother? On the other hand, should the mother be subjected to the dangers of a ruptured uterus and hemorrhage by a version sufficiently rapid to save the baby?

By version the circulation to the fetus is cut off about as soon as the operation is begun. On the contrary, in Cæsarian section the child is removed from the uterus before the placenta is disturbed. Is this not more consistent with a natural delivery than tearing through an ectopic placenta while the child is still in utero?

Thus far the reported cases of Cæsarian section for placenta previa are as follows:

| YEAR. | OPERATOR. | RESULT. |
|---------|---------------------------------------|--|
| ? | Hypes and Hulbert. ¹⁰ | Mother dead; child dead. |
| 1891. | J. M. Sligh. ¹¹ | Mother dead; child dead. |
| 1893. | A. C. Bernays. ¹² | Mother lived; child lived. |
| 1899. | Mattoli. ¹³ | Mother lived; child lived. |
| 1898. | Lawson Tait (Porro). ¹⁴ | Mother lived; child lived. |
| 1900-1. | Donoghue ¹⁵ (2 cases). | One mother lived; one lost. Both children lived. |
| 1901. | C. H. Hare. ¹⁶ | Mother died; child lived. |
| 1901. | W. J. Gillette (Porro). ¹⁷ | Mother lived; child lived. |
| 1901. | P. D. Covington. ¹⁸ | Mother lived; child lived. |
| 1902. | MacCalla (Porro). ¹⁹ | Mother lived; child lived. |
| 1902. | P. J. Conroy. ²⁰ | Mother lived; child dead in utero. |
| 1902. | P. E. Truesdale. | Mother lived; child died in one half hour. |

Thirteen cases are recorded. Four mothers lost, or 44.4%; four babies, or 44.4%.

These figures seem appalling unless a more critical study of each case is made.

All that can be learned of the case by Hypes and Hulbert is that it was done after everything else had been tried.

In the case reported by J. M. Sligh there was a rigid, probably malignant cervix. Tampons, forcible dilatation by steel dilators, Barnes' bags and bimanual version were attempted before Cæsarian section. Mother died twelve hours after operation. The fetus had been dead for two days.

If the result in these two cases teaches anything, it is that Cæsarian section should be done before everything else has been tried or not at all.

Nobody of fair mind would object to ruling out these cases with such histories.

In the eleven succeeding cases, then, the maternal mortality is 22.2% and the fetal 22.2%. Of these eleven, three were Porro operations. All were operated on after alarming hemorrhages had occurred, and many of them when there seemed to be little hope for mother or child by any method of treatment. Therefore these mortality figures cannot, in any way, be justly used for comparison. It would be interesting to know how many, if any, of these 22 lives could have been saved by version.

These results prove that the Cæsarian operation is not contra-indicated when the vitality of the patient is low from loss of blood.

I will report a case in harmony with this statement.

REPORT OF CASE.

Sarah K., thirty-three years of age; married ten years; born in Scotland. Seventh pregnancy. No miscarriage. Previous labors normal.

Last catamenia Jan. 1 to 5, 1902. Labor expected Oct. 10, 1902. Early symptoms were similar to those of former pregnancies. Worked in cotton mill July 1 to 4. After a long walk on July 5 had a slight hemorrhage. On the same day she consulted Dr. John B. Trainor at his office. During the rest of July and during August she was up and about the house. Had slight hemorrhages at intervals of from three days to two weeks. These usually came on after exertion.

Sept. 6 had a moderate hemorrhage accompanied by uterine contractions lasting about two hours. Did not consult her physician at this time, remained quiet for three days, and flowing stopped.

Sept. 16, on account of a profuse hemorrhage, she sent a messenger for Dr. Trainor. He responded promptly, and after a vaginal examination quickly realized the gravity of the case. An ambulance was summoned immediately, and she was

removed to the Fall River City Hospital, arriving at 3 P.M. When admitted to the ward she was bleeding freely. Pulse 128, temperature 99.2°. Absolute quiet, a pad to the vulva and a firm T bandage were sufficient to control the hemorrhage. On the following day, Sept. 17, I was requested to see the patient. At 4 P.M. I saw her for the first time. She appeared fairly well developed and nourished, noticeably anemic. Pulse 112, temperature 99.2°.

The position of the child could not be definitely made out by palpation, although it was thought to be oblique or nearly transverse. The fetal heart was heard loudest to the left, and on a level with the umbilicus. Rate 160.

The pad at the vulva and the sheet about the buttocks were saturated with blood. Vaginal examination revealed slight flow of blood, a few small clots in the vagina. Cervix broad, not taken up, resistant, but not rigid. Pulsations distinctly felt on every side. Os admitted one finger readily, two with difficulty. Placenta was attached all around the internal os, except a small detached area on the right side, which admitted the finger for some depth. Ballottement absent.

It was said that the amniotic fluid had escaped. I called Dr. J. H. Gifford to see the patient with a view to discussing the propriety of performing Cæsarian section. Soon after his arrival, we made another vaginal examination, whereupon a violent hemorrhage occurred.

A firm packing of iodoform and dry sterile gauze controlled the bleeding. The pulse then counted was 140, and feeble.

It was evident that interference of any kind at this time would result in the loss of mother and child. We concluded to temporize for a few hours at least. It was now 5 P.M. At 6 o'clock, pulse was 130, and of better character. Uterus began to contract, and continued at five-minute intervals. The pad at the vulva gave evidence of more bleeding. Morphine sulph. gr. $\frac{1}{4}$ was administered hypodermically. Uterine contractions and flowing ceased.

At 10 P.M. appearance of the patient had much improved. Pulse was 120, and of comparatively good volume. There had been a very little more bleeding, but uterus was beginning contractions again. Fetal heart now 170-180.

Should we temporize longer? If not, what method of interference would offer the best chance for mother and child? The condition of the patient was poor, but she seemed to be on the right side of the dividing line for operation.

More morphia would be required to control contractions, and, inasmuch as there was more show of blood on the pad, it was decided not to postpone interference.

Operations considered were rapid dilatation and version and Cæsarian section. The method selected must be that which would result in the loss of the least amount of blood. Surely this patient had little more in reserve than her last pint, and at this stage it is not the ounce lost or saved that gives the result?

The history of the escape of the amniotic fluid, the abnormal presentation, the central implantation of the placenta, and the undilated os, if not abso-

lutely contra-indicating version, forbode grief as the result of the attempt. As for the Cæsarian section, the risk rested almost entirely in the shock of this operation, and it was concluded that she would withstand this better than the unavoidable hemorrhage attending version.

Accordingly the patient was prepared in the usual way for emergency laparotomy. The ether was administered by Dr. E. F. Curry, and Drs. J. H. Gifford and H. G. Wilbur assisted me.

Operation.—Median abdominal incision eight inches in length. Uterus delivered through the abdominal opening, and thoroughly walled in with gauze towels. It appeared small for an eight-month uterus, but more dense. The second incision was made from the fundus uteri to the lower segment, not cutting into the placenta. The uterine wall was about half an inch in thickness. No amniotic fluid escaped from the cavity.

Baby found lying nearly in transverse position. Cord tied and cut. Child handed to Dr. R. J. Thompson. At this point m. X of ergotine were given hypodermically. The uterus closed down well. Membranes adhered firmly, so that it was necessary to scrape them off with a sponge. Patting the uterus with the hand a few times stimulated it to contract, so that when the placenta was removed, there was scarcely any loss of blood. Two thirds of the placenta lay to the left and one third covered the os. Dr. Wilbur made moderate pressure with the thumb and forefinger of each hand, encircling the cervix, and thereby controlled the very slight bleeding which occurred. The vaginal gauze was removed, and a long sponge was passed through the cervix into the vagina. The uterus was then closed with mass interrupted sutures of silk. The abdominal cavity was flushed with normal salt solution and closed with mass interrupted sutures of silkworm gut. Strychnia gr. $\frac{3}{16}$ and gr. $\frac{3}{16}$, with nitroglycerine gr. $\frac{1}{16}$, were administered during the operation. The patient was apparently in good condition at the end of the operation. Pulse 128; fairly good volume. The child was removed from the uterus within three minutes, and the operation completed in thirty minutes. The baby died in half an hour of asphyxia.

Convalescence was marked by a rise in temperature to 103° on the fourth day; dropped to 101° on the fifth, and then gradually down to normal. Pulse was 112 on the day after the operation, and at no subsequent time was it more rapid. At the time of the rise in temperature there was no abdominal distention, no tenderness, abdominal incision uniting by first intention, and the lochia remained sweet at all times. Vaginal examination revealed nothing. However, it is probable that there was some absorption at the cervix.

At the end of the fourth week the patient was discharged well. Jan. 15, or about four months after operation, I visited her at her home. She was doing her housework, and said she felt as well as ever. The abdominal cicatrix was firm.

The loss of the child was regretted very much, and it seems a question whether or not a further delay of a few hours before operating would have given it a better chance. In interest of the mother, however, this was not done.

It is unwise and unnecessary to do this operation

on a patient *in extremis*, when a firm vaginal packing of dry sterile gauze will control any degree of hemorrhage sufficiently long to allow the woman to recover a fairly good pulse. This is the only time when the vaginal tampon is of any value, for in the mild hemorrhages that occur earlier, the recumbent position with the hips well elevated suffices to stop bleeding.

The technique in the above operation was similar to that used at the Boston Lying-in Hospital.

Dr. A. Palmer Dudley²¹ recommends a more modern method. It is essentially as follows: The gas and oxygen as the anesthetic, saline irrigations instead of sponges. Abdominal incision six inches long from above the bladder to within two inches of the umbilicus. Elastic tubing passed around the cervix to control the ovarian and uterine vessels is drawn tight, half-knotted, and given to the care of an assistant. A second assistant places a hand at either side of the upper angle of the incision, and makes steady, firm pressure against the fundus uteri. The traction made upon the rubber tubing will keep the uterus firmly pressed against the abdominal wall below. The uterine incision is then made.

There are objections to this method, especially for placenta previa, which are quite obvious. In the first place, it is desirable not to cut into the placenta in making the uterine incision, but instead to begin at the fundus and cut down to the placenta. Unnecessary bleeding is thus avoided. To do this the abdominal incision must be long.

The elastic tube drawn tight around the cervix compresses the uterine nerves. Temporary paralysis may result in inability of the uterus to contract, with a resulting hemorrhage that may necessitate a Porro.

Gillette¹⁷ was obliged to do a Porro on account of hemorrhage resulting from the inability of the uterus to shut down. He used a rubber tube drawn tightly around the cervix and tied. The hemorrhage was attributed to anemia, but was it not more probably due to pressure paralysis of the uterine nerves?

In cases where placenta previa is suspected I wish to emphasize the importance of rigid cleanliness in making vaginal examinations. The hair about the vulva should be removed, the external genitals scrubbed with green soap and water, then with lysol or corrosive sublimate solution. An antiseptic douche should be given. The examination should be made with rubber gloves, for the finger goes into a perfect culture medium for bacterial growth.

The recent progress in obstetrics may be very materially attributed to the adoption of the principles of modern surgery, and in the operation of Cæsarian section is found a relief for a hitherto unsatisfactory treatment of a formidable type of placenta previa.

In conclusion, then, the Cæsarian operation would seem to be the best treatment for placenta previa, complete or partial, when the child is viable, and when the diameters of the pelvis or the conditions of the soft parts render the operation of dilatation and version, performed with sufficient rapidity to save the child, a dangerous procedure for the mother.

FURTHER REMARKS ON THE TREATMENT OF PLACENTA PREVIA.¹

BY FRANK A. HIGGINS, M.D., BOSTON,

Instructor in Obstetrics, Harvard Medical School; Senior Physician to Out-patients, Boston Lying-in Hospital; First Assistant Visiting Physician for Diseases of Women, Boston City Hospital.

It is not my intention to weary this society indefinitely by the discussion of a subject to which it has already devoted considerable time, but so long as the proper treatment of placenta previa remains a matter of doubt to many in the profession, and so long as such widely different views as to its treatment are held by the members of this society as was evinced at a recent meeting, any further evidence which one can bring to bear on the subject can scarcely be out of place.

Since the first of January of this year I have seen and operated upon five cases of placenta previa. Two of these were of the partial or marginal variety, while three had complete placenta previa. All five of the mothers made excellent recoveries and without complications. All five of the infants were born dead or died soon after birth. One of the five possibly might have been saved under a different method of delivery, but in only one of the cases did the fetus before delivery appear to be in such a condition that any hope of its survival could be entertained. In three of the cases the patient was at full term, but in two of these the fetal heart could not be heard at any time, and whatever chance the third child might have had was deliberately sacrificed for the sake of the mother, her life being considered of much greater importance. The other two cases were hopelessly premature. Therefore in all the cases I proceeded with only one aim—that of making the operation absolutely safe for the mother, so far, of course, as it is ever possible to do so.

Of the two cases of partial placenta previa the first was seen Jan. 10, at the Lying-in Hospital, having been brought in by Dr. Denny of Brookline, who packed the vagina to control the hemorrhage. The patient had lost considerable blood, and was still bleeding slightly. No fetal heart could be heard, and there was no pulsation in the cord. The mother being in fair condition, I delivered her immediately by version, and rapid recovery followed. It was my intention to allow the body to slowly follow after extraction of the foot, but its small

¹ Read before the Obstetrical Society of Boston, Jan. 20, 1903.

size and strong uterine contractions caused rapid delivery.

The second case was seen on Feb. 22 in the outpatient clinic of the Lying-in Hospital, and was one of partial previa. There had been considerable hemorrhage for four days and a large hemorrhage of at least a quart before the patient sent for assistance, the bed being saturated and containing many clots. The hemorrhage was controlled for a number of hours by vaginal packing, and the patient's condition improved so far as possible. Later a small amount of ether was given, the hand was inserted into the vagina, the os then about the size of a quarter was dilated to admit two forefingers, enabling me to bring down a foot, assisted by the other hand through the abdominal wall. The foot was drawn outside the vagina and held firmly, exerting steady and moderate traction. The patient was allowed to come out of ether after the foot was secured, and delivery was accomplished in about an hour and a half with no further loss of blood and practically no shock to the patient. The child was, of course, stillborn. The fetal heart was heard just before the operation, but on account of the mother's poor condition everything was done with her safety in view.

Of the three cases of complete placenta previa, the first case was seen in consultation with Dr. Parks of East Boston on April 16. The patient was about six and one-half months pregnant, when without any warning symptoms she had a sudden severe hemorrhage of an alarming nature. On examination the os was found about one half dilated and completely covered by placenta. The patient was removed to the hospital. Version, the placenta being perforated, and immediate delivery were performed. The child breathed for a few minutes, but it had not arrived at the viable period.

The second case was seen Aug. 22 with Dr. Duff of Charlestown, who first saw the case after she had been bleeding for ten hours. The vagina was packed, and the patient removed to the hospital. The os was about two inches dilated and completely covered with placenta; the fetal heart could not be heard, although carefully searched for several times. The patient's pulse was 124, and she had evidently lost considerable blood, yet she was in fair condition. I felt, however, that slow delivery would be better for her than rapid version and delivery, especially as there seemed to be no question but that the fetus was already dead. The placenta was perforated, a foot brought down and steady traction made on the thigh. As the body appeared, the child was seen to make an attempt at respiration so that delivery was immediately completed. The child could not be resuscitated, it was in a state of pallid asphyxia, probably from loss of blood, and made only a few spasmodic attempts at breathing. If I could have determined before operating that the fetus was living, possibly more rapid delivery might have saved this baby, but I do not think it probable, because of the amount of placenta separation.

The third operation for complete placenta previa was done on Oct. 3, at the Deaconess Hospital, the patient having been brought in from Milton in order to be in a safe place in case of a serious hemorrhage. After several weeks of quiet and moderate hemorrhage, the patient was finally delivered, as she

was gradually losing ground. Manual dilatation sufficient to admit of bringing down a foot, perforation of the placenta and slow delivery were easily accomplished with very little loss of blood. The size of a six-months fetus, however, offered little obstruction to the delivery, which took about thirty minutes.

I am perfectly aware that the reporting of these cases can have only comparatively little effect towards the settlement ultimately of the best treatment for placenta previa, but to my mind they do help to clearly demonstrate the great safety to the mother of the slow delivery, after slight dilatation of the os, and the extraction of a foot.

I am also more than ever convinced of the comparative low maternal mortality, even in complete placenta previa, when the patient is taken in charge and receives proper treatment immediately after the first hemorrhage, and that the chief danger lies in repeated or continuous hemorrhages. The great objection to slow extraction is that it means the death of the fetus, but until we have some other expedient equally safe for the mother, and which promises better results for the infant, I shall continue to advocate and practice this method. Traction on the foot in the manner described effectually prevents hemorrhage, and at the same time slowly dilates the os, and the body of the child gradually emerges from the vagina. The time for delivery in my cases after extraction of a foot was allowed to occupy from twenty minutes to an hour and a half.

I would not advocate slow delivery in every case. If the mother is in good condition and the fetus also, as indicated by the fetal heart beat, full manual dilatation and rapid extraction should by all means be performed. But if the fetal heart cannot be heard, it is usually fair to assume that the child is not living, and the mother should be safeguarded in every possible way.

We have been inclined to believe that it is only the cases of complete placenta previa in which there is much of any danger to the mother. I desire to emphasize the fact that this is not so. Of these five cases the two with partial placenta previa were the ones in the most serious condition; not because of the situation of the placenta, but because of the neglect of the hemorrhage.

Perforating the placenta to do version I have found to be an easy matter, causes no maternal hemorrhage and very little to the fetus. The under surface of the placenta is divided into lobules with sulci running between, and the placenta is easily separated and perforated at the sulci. In my experience this is better than trying to separate the placenta, and going to one side of it.

As in my previous paper I advocated packing to control hemorrhage, I would say a word more of caution against placing too much dependence upon it. Packing is of value mainly as a temporary expedient to control hemorrhage, to promote dilatation, or to gain time while getting ready for an operation, or before moving a patient. If properly and firmly applied it will control hemorrhage for a few hours, but not longer. I would also insist that the packing be inserted with the patient in Simms' position, as it cannot be properly applied with the patient in the lithotomy position. I have seen repeated failures of the packing to control hemorrhage

when it has been put in through a bivalve speculum with the patient on her back.

With respect to the treatment of placenta previa by Cæsarean section I have yet to see a case in which I think it would be advisable or justified, and such will, in my opinion, be rarely seen.

The only occasion for Cæsarean section in placenta previa I would define as in my former paper: complete placenta previa with mother and child both in good condition before the occurrence of severe hemorrhage, and with the os uteri undilated.

This short paper, practically as it stands, was prepared for the meeting of the Obstetrical Society last October, but was deferred because of other material. Since then I have had one operation for placenta previa at the Boston Lying-in Hospital, which proved fatal to the mother, the first one in twenty cases.

The patient, a young primipara, was seen on the afternoon of Dec. 4. She had had considerable hemorrhage, and the pulse at that time was 130. She was at term. The fetus was in good condition, os dilated about two inches, completely covered by placenta. Notwithstanding the patient's rapid pulse, from her appearance I thought she would stand immediate delivery without encountering serious difficulty. Version was performed, and immediate extraction, and a living child obtained. The mother died, however, in a few hours after delivery, from shock and hemorrhage. The loss of this patient I attribute to my error in judging the patient's condition. I believe that she might have been saved had I packed and delayed delivery until she was in better condition for operation, or had I brought down a foot and allowed slow delivery at the sacrifice of the child.

NOTES ON X-LIGHT.

BY WILLIAM ROLLINS, BOSTON, MASS.

THE EFFECT OF X-LIGHT ON THE CRYSTALLINE LENS.

EXPERIMENTS have been reported in this JOURNAL which showed that animals could be made blind by x-light. Through correspondence with investigators, who at different periods have worked with x-light, I have learned of a number of cases where the eyes had grown prematurely old during the investigations. Recently I have had occasion to examine a man who has been exposed to x-light to a considerable extent since 1896. Though he is less than forty years of age he had given up trying to read even a daily paper, because he could not see the letters. To enable him to see his work comfortably at a distance of forty-three centimetres, it was necessary to provide him with double convex glasses, number 26.

With the exception of Professors Trowbridge's great condensers and Tesla's high frequency generators, the apparatus used in my experiments to help Dr. Williams in his work has been the most powerful employed in the production and study of x-light. That I have escaped injury has been due to an early recognition of the dangerous nature of x-light, and to having taken the precautions recommended in earlier papers. These uninteresting personal matters are mentioned only to give an opportunity to repeat some of these precautions which

have now become sufficiently obvious to be called x-light axioms.

First axiom: No x-light should strike a patient except the smallest beam that will cover the area to be examined, treated or photographed.

Second axiom: No x-light should strike the observer.

Directions for constructing apparatus to meet these conditions have been given. A few points will bear being repeated.

The x-light tube must be in a non-radiable box from which no x-light can escape except the smallest beam that will cover the area to be examined, treated or photographed. The box must have a nonradiable diaphragm plate, the opening in which can easily be adjusted, while looking in the fluoroscope, until the beam of light is the smallest that will cover the area under examination. The cryptoscope must have a plate of heavy lead glass to absorb the x-light which has passed unchanged through the fluorescent screen, to prevent injury to the observer's eyes. The walls of the cryptoscope must be made of nonradiable material. The patient should be covered during photographic exposures with a nonradiable sheet, exposing only the necessary area. An experimenter who works much with x-light should use a nonradiable face mask, the eyeholes of which are glazed with thick plates of heavy lead glass. In using the cryptoscope, while testing the tube during pumping and tuning, he should not use his hand for examination, but should attach to the cryptoscope a Roentgen gauge and a Williams fluorometer for determining the penetrating power of the x-light and its brightness. The hand that holds the cryptoscope should be protected with a nonradiable covering. During the pumping and tuning of x-light tubes, they should be kept in an oven with nonradiable walls. Most of these precautions are neglected even at the present time, as may be seen by the illustrations in the catalogues of the makers of apparatus and in the papers and books of those who are writing on the subject, where open tubes are almost invariably figured. If masks are used to protect patients during the therapeutic application of x-light, they are in many cases made of rubber cloth or other radiable material. If speculas are used in treating the cavities of the body, they are often made of radiable celluloid. Rubber or celluloid to make them suitable must be mixed with heavy metals or their compounds. That inefficient means are still employed to protect patients is partly due to attempts to ignore or disparage the crucial experiments that have been reported on the effects of x-light on animals. These experiments showed not only that x-light could burn, make blind and kill, when all other forms of energy that could produce the results were excluded, but they also showed that under the conditions present during the proper use of x-light in therapeutics, other kinds of energy need not be considered in the light of causes of serious injury to patients. Therefore, attempts to protect patients should consist in protecting them as far as possible from the light itself. Another matter to which attention should be directed is the importance of making all the apparatus used about patients during therapeutic applications of x-light of materials which will allow them to be sterilized. Some of the diseases for which x-light is used are known to be contagious, and while it is generally con-

sidered that cancer is not contagious, it is to me an interesting fact that several persons who have been treating this disease by x-light have themselves been attacked. I believe this would not have happened if proper precautions had been taken. It is, to say the least, unwise to be constantly treating cancer and other diseases by x-light without regularly fumigating the room and keeping the cryptoscope and other appliances sterile. Great hospitals in which the necessity for contagious wards is clearly recognized still consider one room, which is not fumigated, a proper place in which to make not only all diagnostic but all therapeutic applications of x-light, and to make them with apparatus which is not sterilized in many cases. In fact, to sterilize the present forms of much of the apparatus in use would be difficult by heat, which is the simplest method. It would appear to be at least reasonable to take advantage of such power as may reside in formalin vapor to fumigate the x-light room every night, and to make the instruments used about patients of such material as will permit heat to be used to sterilize them. I have described cryptoscopes, seehears and stethoscopes, light concentrators, light benders and specula which can be sterilized in this way.

Clinical Department.

MASSACHUSETTS GENERAL HOSPITAL.

(Concluded from No. 13, page 346.)

Dr. MIXTER reported on

A CASE OF LAMINECTOMY FOR BROKEN NECK.

The patient, a strong, healthy man, fell from a tree, some six or eight feet, to the ground, striking on his head. I saw him the next morning at the hospital, and in spite of the fact that the consulting neurologists looked upon it as an almost hopeless case, I decided to operate at once.

There was complete loss of motion and sensation, corresponding to a lesion of the cord in the injured region, and the temperature had already begun to rise.

The fracture was in the usual place, the fifth and sixth cervical vertebræ, and in addition to several fractures the laminae were dislocated.

After removing the broken fragments on thoroughly exposing the dura, the latter was opened and the cord examined. No gross sign of injury was found. The dura was not closed, and the wound was drained with a small gauze wick.

He has already good motion in one leg and in his arms, and is still improving. Dr. Walton will tell you more accurately his condition.

This case seemed as unfavorable as possible before operation. While it cannot be absolutely proved that operation is the means of cure in these cases, the fact that ones like this do get well convinces me that it is the surgeon's duty to operate on all cases if they can be seen early.

One point on which I wish to insist is the good effect of leaving the dura open and draining the cord.

DR. WALTON: The question of operation in this case presented itself shortly after I had read a paper to the Society for Psychiatry and Neurology accepting the opinion of those surgeons who advocate free operation in case of spinal fracture, without laying too much stress upon theoretical considerations, the only counter-indications to operation being great displacement, rapidly rising temperature and moribund condition. This case seemed to offer one of these exceptions on account of the high temperature and general condition. Dr. Mixter decided to operate notwithstanding these counter-indications, and the result has fully justified his position.

Many authorities have held that complete paralysis, motor and sensory, to a certain level, indicate complete and irremediable crush of the cord, and that operation in such event is unjustifiable. This position is untenable, for Dr. Mixter's case is by no means the first in which marked improvement has followed these symptoms. All authorities agree that it is sometimes justifiable to operate in case of incomplete lesion of the cord, and Kocher advises operating later in case improvement has shown incomplete lesion; but if operation is to be undertaken at all, surely the earlier the better, before adhesions are formed, and since we cannot positively establish complete crush it seems wise to give a patient in so serious a condition the benefit of every doubt.

There was paralysis of all forms of sensation to a little above the nipple line, complete loss of motion and reflexes in the lower extremities and motor and sensory paralysis in the upper, such as pointed to a lesion at the level of the fifth and sixth cervical vertebræ. Improvement was gradual after the operation, the lasting symptoms being practically of the Brown-Sequard type. There is still complete absence of motion in the left leg, but very good motion in the right leg, including the movement of the tibialis anticus, though outward movement of the foot is impossible. Tactile sense rapidly returned on both sides; pain and temperature sensation have gradually returned on the left, but are still impaired upon the right, muscle sense is absent on the left and very slightly impaired on the right. The kneejerks are exaggerated on both sides and ankle clonus is present without the Babinski sign (a very uncommon finding). The movements of the arms are very good, though still greatly impaired, and all forms of sensation are impaired on the ulnar side of each hand. This distribution of paralysis indicates lasting lesion on the left side of the cord, involving both gray and white matter, and lasting lesion in the gray matter of the right side with very slight remains of injury to the white matter on the right side. The loss of muscle sense on the left is explained by the fact that the fibers conveying these senses do not cross until they reach the medulla. Loss of pain and temperature sensation on the right and presence on the left show that the fibers conveying these sensations cross shortly after entering the cord. The speedy return of tactile sensation on both sides would tend to show that tactile fibers are of wide distribution and of partial decussation, for if they ascended in one bundle, whether crossing or not crossing, there should be loss of this variety of sensation in one side or the other.

It may be argued that inasmuch as the crush of the cord in this case was incomplete, the result would have been equally favorable without operation, and this position can never be disproved in an individual case. Statistics show, however, that there is a greater percentage of recovery among the cases operated upon than among those without operation. It is practically certain, therefore, that in some of these cases operation is beneficial, and the whole history of this case inclines us to regard it as one in which operation was of signal service.

DR. F. C. SHATTUCK showed a case of probable

ADDISON'S DISEASE.

This patient has for five months been losing strength and weight without assignable cause. During this time a discoloration of the skin has come on. He has had some digestive symptoms, but the prominent features are weakness, loss of weight and discoloration of the skin. The discoloration is perfectly uniform except that the eyelids are more deeply discolored. The discoloration is not patchy, and the mucous membranes are not involved. His occupation is barbering, and he has worked and lived in Danvers. There is no reason to think that he had anything to do with arsenic. It is not the sort of discoloration we see with lead jaundice, and he has none of the usual symptoms of lead poisoning. The question is whether he has Addison's disease or not. The genitals, axillae and linea alba are not more pigmented than any other portion of the body, as they are apt to be in Addison's disease. He has had slight fever, 100 or more. We know that Addison's disease is a destructive disease of the adrenals, and the most frequent cause is tuberculosis. In this case there are no signs of tuberculosis anywhere. I gave him an injection of tuberculin, and his temperature rose to 104 within twenty-four hours, which is pretty strong evidence that there is tuberculosis about him somewhere that we have not found. I am inclined to believe that he has Addison's disease. I have given him the iodide of potassium for a week, and am having his urine examined for arsenic and lead. He is also having suprarenal extract. I have had one case recover under the extract.

[NOTE.—Written two weeks after the malaise due to the tuberculin injection had disappeared, the patient showing marked gain. Digestive symptoms are absent; strength has increased; the discoloration is distinctly less; there has been some gain in weight. A very slight trace of lead was found in the urine. Arsenic is not yet reported on.]

DR. C. B. PORTER next demonstrated the following cases:

CASE I. CURE OF LARGE VENTRAL HERNIA IN RIGHT UPPER QUADRANT.

The first patient is a policeman. Two years ago he was operated upon for a stab wound of the liver. The abdominal muscles never regained their tone subsequent to this operation, and a general bulge in the right upper quadrant of the abdomen followed. An attempt was made four months later to cure this bulge, but without success. During the past two years the patient has been incapacitated for heavy work. Besides this he suffers from increasing constipation. During the three weeks previous to his entrance he had several severe paroxysms of pain in the region of the hernia associated with vomiting.

Cathartics were ineffective, and operation was advised to forestall the absolute shutting off of the bowels. At the operation the intestines were found inextricably tangled and adherent to the abdomen in the region of the old wound. These adhesions were dissected away with great difficulty, and the bowel injured in several places. Owing to the injury done to the small bowel, it was found necessary to resect thirteen inches and do an end-to-end suture. After this a radical cure of the hernia was done. The operation took six and one-half hours. The patient was on his feet in two weeks, the bowels working perfectly, the abdominal wound firm.

CASE II. AMPUTATION OF WHOLE UPPER EXTREMITY FOR CHONDRO-SARCOMA.

The second case is a young man twenty-five years old. Twelve years ago he first noticed a gradually increasing pain and tenderness in his left shoulder.

He was admitted to this hospital at that time, and a tumor of the shoulder found. It was finally decided that the case was inoperable, and the boy was discharged. During the succeeding years the patient enjoyed good general health and did heavy work. The shoulder grew steadily in size, until three months ago a fungating growth made its appearance in the left axilla. After the appearance of this tumor the patient became progressively weaker. He worked, however, until about two weeks ago, when he was recommended to the hospital. The left shoulder as seen by the specimen and the photograph passed around is the seat of a large stony, hard growth. This mass invests the outer two thirds of the clavicle in front, while in behind the scapula is completely buried. On the surface of the mass is a network of large superficial veins running horizontally. The posterior part of the axilla is filled with an exuberant growth the size of the fist. Scarcely any motion has been present in the shoulder joint for some years. The dangers of the operation were carefully explained to the patient. He was urged to take time to make up his mind. He elected to take his

chances as there was really no other alternative, except a lingering illness, to end finally in death.

Complete amputation of the upper extremity, including clavicle and scapula, was done. There was scarcely any bleeding during the operation, as the growth had compressed even the axillary vessels. The denuded area was covered by flaps and grafts.

The patient never rallied after the operation, and died in shock three hours later. At the autopsy

metastases were found in the lungs. Cultures from the heart showed streptococci. The invasion of bacteria evidently took place from the fungating area in the axilla.

AUTOPSY BY J. W. WRIGHT.

Anatomical diagnosis. — Amputation of left upper extremity for sarcoma in the region of left shoulder. Metastatic sarcoma of lungs. Hyperplasia of the spleen. Slight chronic interstitial nephritis. Slight defective closure of the foramen ovale. Streptococcus septicemia.

Microscopical examination. — A section of lung substance including tumor nodules shows that the tumor is composed of dense connective tissue and of cells with interlacing processes; the neoplasm is regarded as a fibro-sarcoma.

CASE III. DOUBLE DISLOCATION OF HUMERUS WITH FRACTURE OF SURGICAL NECK OF EACH.

The third case is a very fat man, who fell down stairs one month ago. Since the fall both shoulders have been useless. On examination sub-coracoid dislocations of both humeri were found. No fractures were made out. Movement of the arms were extremely limited. X-rays were taken of both shoulders, but although the dislocations were found they gave no evidence of fracture. Operation was done by me Oct. 11. An effort was made to reduce the dislocation of the right shoulder, but outside of gaining freer motion in the shoulder joint no improvement in the position was effected. An incision was made in the anterior surface of the shoulder joint, and a fracture of the surgical neck of the humerus discovered. The head of the bone was

taken out. Two weeks later reduction of the left shoulder was attempted under ether; but this was also unsuccessful. On cutting down in the same manner as in the right, a fracture of the surgical neck of the left humerus was found. The head of the bone was excised in the same manner as at the first operation. A week after the latter operation the patient was discharged against advice. Both wounds were healing by first intention. He returned in a month after his discharge with great improvement in the motion of both shoulders. I show him tonight two weeks after his last appearance. As you see, he can lift his right arm to a

horizontal position, and is gaining fast the use of his left.

CASE IV. HORSESHOE KIDNEY MISTAKEN FOR TUMOR OF STOMACH.

This woman is thirty-one years old and was recommended by Dr. H. F. Hewes for probable cancer of the pylorus. She has had a history of occasional pyrosis after eating, associated with abdominal pains. Sometimes she vomited during these attacks. Examination of stomach contents showed no free hydrochloric, lactic or butyric acids. No cachexia or loss of weight has been present. A tumor is made out in the epigastrium in the median line, not movable nor tender. The patient wished an operation in order to decide whether or not cancer was present. A laparotomy was done by Dr. C. A. Porter, when all the abdominal contents were found normal. There was, however, a connecting band about one inch in thickness, extending across the vertebral column and joining the inferior poles of both kidneys. It was this mass that had been palpated through the abdominal wall.

CASE V. MULTIPLE FRACTURES OF FOREARM.

On October 22 this man caught his right arm in a revolving belt. The x-ray plates show a transverse comminuted fracture at the middle of both the radius and the ulna with over-riding. The lower end of the radius was also transversely fractured with an anterior displacement of the lower fragment. The lower end of the ulna was dislocated outward over the radius, but not fractured. The upper fracture was compound on the inner aspect of the forearm. An opening was made over the posterior border of the ulna at the point of fracture. Both bones were wired into place and the wound closed tight. A counter opening was made on the flexor surface of the forearm to relieve the tension of the skin from swelling. Firm extension was applied, and the lower deformity molded into place without difficulty. The wounds healed by first intention, and an x-ray, taken twenty-six days later, shows the position of the fragments to be excellent. The multiple fractures and the injury to the soft parts made it seem almost hopeless to save the arm.

CASE VI. LARGE HYDATID CYST OF LIVER, COMPLICATED BY NUMEROUS ONES IN BOTH LUNGS.

The last case is an Armenian, forty years old. For ten weeks he has complained of his stomach and intestines. The bowels were irregular, but no vomiting was present. For three weeks there was loss of weight and strength, with increasing pain in the abdomen. No chills noted. On examination patient was seen to be emaciated and sweating. No glands were enlarged. Dullness was present in front from the fourth rib on the right to four fingers' breadths below the right costal border. The right hypochondrium and the epigastrium were occupied by a smooth, round bulging mass that extended nearly to the umbilicus. Fluctuation was easily made out over the most prominent part of the tumor. In this point the tenderness was pronounced. Palpation over the tumor gave a sense of crepitation beneath the fingers. Litten's phenomenon was marked on the left side, but absent on the right. In the back the dullness extended from the base to the angle of the scapula. Temperature 96.6°, white count 16,000, hemoglobin 50%. Bile present in the urine.

At the operation the tumor was seen to be a large, bile-stained liver. This was aspirated and pus found. A wide opening made along the trocar was followed by a gush of thin, brownish fluid, which contained numberless small daughter-cysts, some still unruptured. The size and color of most of these cysts resemble that of white grapes, while the sac of the main cyst was pearly white and adherent. As the condition of the patient was poor, the sac was packed full of gauze and the man put to bed. Two days after the operation symptoms suggesting pneumonia developed. Temperature 105, pulse 150, respiration 40. The area of dullness in the right base was unchanged and no other signs in the lungs were made out. For two days the man ran a high temperature with delirium, gradually becoming weaker until his death, four days after the operation.

Autopsy showed both lungs to be invaded by arger and smaller cysts filled with brownish fluid.

Dr. J. H. WRIGHT had examined a piece of the tumor excised before amputation, and found that it was essentially a spindle-cell sarcoma with a considerable development of fibrous tissue.

A later examination of the tumor, after amputation, showed that the main mass of it was bony in character.

Dr. C. L. SCUDDER: I have no cases to show, but wish to speak of two groups of cases of operation on the knee. The first group represents that class in which a movable semi-lunar cartilage caused trouble, and it seems to me very interesting that seven cases were operated on, and there were no recurrences except in one case.

The second group represents an entirely different class, that is, those cases in which movable bodies were found. They were removed, and in some instances were found to be hypertrophied fringes, which caused mechanical irritation, and in other cases, small exostoses. Periods from one to four years have elapsed since the operations were done, and in only one of these twelve cases has there followed complete relief; in other words, symptoms have recurred and persisted; such as swelling, pain and weakness in the joint, with at times, locking of the joint.

These two groups are distinctly different. The first group represents a distinct mechanical difficulty successfully treated by operation. The second group suggests a general disturbance in the joint rather than a purely mechanical difficulty, the mechanical disturbance being purely symptomatic. To the surgeon, from a clinical point of view, it indicates also the need for a thorough exploration of the joint in order to determine the pathological condition and to throw some light upon such disturbances.

I think work is being done with which Dr. Goldthwait is familiar, in regard to these joints, and I should like to ask him what the pathological findings are and why these cases do not recover after the loose body or synovial fringes have been removed. Is not the local condition suggestive of some general serious trouble progressing?

J. E. GOLDTHWAIT'S DISCUSSION OF DR. SCUDDER'S PAPER.

Dr. J. E. GOLDTHWAIT: I hope that Dr. Scudder in reporting these cases will give a careful description of each case. Without such description the cases have little value.

In the so-called "fringe" cases, or the joint cases in which there are loose bodies, it is to be borne in mind that the fringe or the loose body is usually a symptom of disease and not the disease itself. The fringe may be the result of tuberculosis, rheumatoid arthritis, simple traumatism or any other disease or irritative condition. The loose body may be and commonly is an exostosis which has been broken away from its attachment, and represents commonly a symptom of osteo-arthritis.

It is evident from this that simple removal of the fringe or the loose body should not be expected necessarily to cure these cases. The surgeon in operating should consider all the features and should expect a perfect result or a partial improvement, depending entirely upon the nature of the

condition which produces the special lesion for which the operation is performed. It is only during the past six weeks that I have operated upon a man, taking from each knee a mass of fringes large enough to fill the palm of the hand. The fringes resulted in this case from rheumatoid arthritis. The man is not, of course, cured of his rheumatoid arthritis as the result of this operation, but the amount of improvement which has resulted from the operation is a source of gratification to him.

In another case, a comparatively short time ago, a fringe was removed, which resulted from trauma, together with a large lipoma arborescens, which had formed as the result of a degeneration of some of the fringes. This condition, resulting purely from trauma, has been followed by perfect results, and the man today is an active athlete.

If such operations are discussed with this understanding, it seems to me there need be no confusion or disappointment in the ultimate results.

Reports of Societies.

NEW YORK NEUROLOGICAL SOCIETY.

STATED meeting, March 3, 1903. PEARCE BAILEY, M.D., President.

TABES ASSOCIATED WITH HEMIPLEGIA.

DR. JOSEPH COLLINS presented a man, forty-two years of age, a bartender by occupation. When twenty-four years old he had had a chancre, for which only treatment was given. A year later an iritis developed, and disappeared after two months' treatment. There was nothing further until eight years ago, when he was seized with an attack of vertigo, which was associated with an aphasia lasting several days. There was no paralysis. Four years later there was a similar attack associated with vomiting. Last August the man fell in an attack in which he was only partially unconscious. Examination showed a right-sided hemiplegia, and this had continued ever since. On coming to hospital there was found in addition a very marked atrophy of the right shoulder and an absence of both knee jerks. The pupils were small and regular, and reacted to accommodation but not to light. There were incontinence of urine and manifest ataxia. The case was presented as one of tabes, the latter probably antedating the attack of thrombosis from which the hemiplegia originated. Coincident with the attack of cerebral thrombosis there must have been an obliteration of one of the cornual branches of the anterior spinal artery. In reality, this case presented three conditions: tabes, cerebral thrombosis and a destructive poliomyelitis of very limited extent. Tabes and hemiplegia were rarely associated.

DR. J. RAMSEY HUNT said that he had examined this case in the city hospital. He had been doubtful about its being an anterior horn disease, and inclined to the opinion that there was a plexus lesion.

DR. M. G. SCHLAPP said that in some of these cases of hemiplegia certain groups of muscles were markedly atrophied. The electrical examination

should decide whether the case was of central or peripheral origin.

DR. J. FRAENKEL said that in only a few of the cases of tabes with hemiplegia had the knee jerk returned, and this had only been temporary.

DR. C. L. DANA said that he had had a short time ago under observation a man with tabes whom he had seen the very day of the occurrence of the stroke. There had not been any return of the knee jerk, and he thought this could only occur in the early stage.

DR. COLLINS said that there had been no suspicion of the existence of tabes before he had examined this man, and he had been deeply interested in the presence of the marked muscular atrophy.

A CASE OF MAJOR HYSTERIA (?).

DR. COLLINS then presented a woman, forty-four years of age, a cook by occupation. There was no history of alcoholism or of venereal disease. The present trouble began four years ago with an involuntary twitching of the hands and a loss of sensation in the hands and arms. This loss of sensation had gradually spread over the entire body. She had no pain, but felt tired and walked with difficulty. The gait was not strictly ataxic, but was rather shuffling and choreic. There was a peculiar condition of the left lower extremity, the lower third being shrunken without any hardening or thickening of the skin. Examination showed universal analgesia and more or less thermal anesthesia and analgesia. The knee jerks and ankle jerks were exaggerated. There was slight disturbance of speech but not of intellection. She presented none of the ordinary stigmata of hysteria, and the color fields were of normal size. The woman had not improved under hospital treatment. According to the history her father and sister were similarly affected, but the former lived to be over seventy years old. The case was presented without a positive diagnosis, because it did not seem to him to correspond either to hysteria, syringomyelia or Huntington's chorea.

DR. SCHLAPP was of the opinion that the case was one of hysteria, because the condition did not correspond to any known pathological lesion. The condition of the leg might have been brought about by a self-inflicted trauma. Two years ago he had presented to the society a case of supposed atypical zoster, but subsequent investigation showed that the patient had produced the condition herself by means of carbolic acid.

DR. R. H. CUNNINGHAM said he was reminded of a number of cases that he had had in a family in Richmond, Va., in 1893. Choreic symptoms developed between the ages of fifteen and thirty in the father, two sons and two daughters. One of the daughters had hemianesthesia. He would look upon the case just presented as one of adult chorea.

DR. COLLINS said that he had been inclined to look upon the case as one of hysteria, yet this diagnosis presented many difficulties. After having observed her carefully for several months he was still more inclined to the diagnosis of major hysteria.

DR. PEARCE BAILEY said that he thought the ataxic gait was due to the anesthesia, and that the case was one of major hysteria. With regard to the other case, there seemed to be no doubt that the atrophy of the shoulder was distinct from the tabes.

A fall on the point of the shoulder was quite frequently the cause of a paralysis with just such an atrophy.

A CASE OF SPINAL TUMOR.

DR. M. G. SCHLAPP presented a man, forty-four years of age, with a good previous history. About two years ago a peculiar twitching had been noticed in the muscles over the right shoulder, and about two months later he had begun to suffer pain at the root of the neck and extending into the trapezius muscle. After a time the right arm became weak, and subsequently the left side. This weakness was found to correspond to the muscles supplied by the anterior and posterior thoracic nerves on both sides. There was the Babinski symptom on both sides. There were analgesia and diminished temperature sense on the left side. The diagnosis made was an extramedullary tumor involving the fifth and sixth cervical roots of the spinal cord, pressing upon the pyramidal tracts and on Gowers' tracts, diminishing the pain sense and temperature sense. The tumor lay on the right side, and probably involved the motor roots on the other side. He thought an intramedullary tumor could be excluded. The man was to be operated on next week.

DR. PEARCE BAILEY said he had seen this man last fall, and at that time there was no sensory disturbance, and the pain dated back two years, but with intermissions. He had formed the opinion then that there was a degenerative lesion rather than a tumor.

A CASE OF CEREBELLAR TUMOR.

DR. J. RAMSEY HUNT reported a case of cerebellar tumor with degenerations of the posterior columns. The subject of this report was a man of forty-six, who had been admitted to Bellevue Hospital in July, 1902, with typical symptoms of cerebellar tumor, although the tumor could not be localized. The cerebellar symptoms had begun three months before, and he was under observation for three months. During these six months there was a progressive diminution of the knee jerks and Achilles jerks on both sides. It was thought to be due to degenerations in the posterior columns of the cord, as had been described in connection with tumors in the posterior fossa of the skull. There was very marked choked disk, and the man's mental condition became one of apathy and somnolence. At the autopsy two small tumors were found, one springing from the dura mater in the median line, and encroaching somewhat upon the right frontal lobe, and the other tumor in the left cerebellar hemisphere. Both tumors were medium-sized round-cell sarcomata. The spinal cord presented evidence of greatly increased intracranial pressure. Specimens of the spinal cord, both transverse and longitudinal, were prepared, and they apparently showed degenerations of the posterior columns, such as had been described in connection with tumor. The higher levels of the cord were most affected. Lissauer's column was spared, as was the rule. The fibers in Clark's column were also usually spared. These degenerations arose from the entrance of the posterior roots into the spinal cord. It was an anatomical fact, that where the posterior roots perforated the dura mater obliquely there was a constriction, and that here the sheath of Schwann was lost. At the same time

there was a constriction of the myelin substance, and some of the fibers were deprived entirely of this substance. The speaker then briefly discussed the mechanical and toxic theories, and said that he presented the case as one favoring the mechanical theory.

A CASE OF CEREBELLAR TUMOR.

DR. L. PIERCE CLARK reported the following case: The subject was a man of thirty, who had had both gonorrhea and syphilis, and who used alcohol and tobacco to excess. The present illness began in October, 1901, with headache in the right occipital region. After a time he began to vomit in the mornings, and the right side became weak. Iodide of mercury had been given without benefit. On examination, there was choked disk in the right eye; the sixth nerve was bilaterally weak; the muscles of the right leg were stiff and painful; the head was held stiffly and bent slightly to the right side; all the deep reflexes were exaggerated, particularly on the right side; there was double Babinski; the gait was characteristically cerebellar. A diagnosis was made of a syphilitic tumor in the middle lobe of the cerebellum involving the peduncle. On admission to the Presbyterian Hospital in January, 1903, for operation, an x-ray examination showed the tumor. The man died rather suddenly, and the autopsy disclosed a tumor of the cerebellum. Between it and the fourth ventricle was a large cyst filled with slightly turbid serum. Apparently the growth was a syphilitic gumma that had undergone syphilitic and calcareous degeneration.

A CASE OF SPINDLE CELL SARCOMA OF THE DURA CEREBELLI.

DR. B. ONUF reported this case, and presented a specimen. The subject of the report had been first seen on May 2, 1902, and at that time complained of a shooting pain in the left ear and in the teeth, and of attacks of dizziness. There was only slight perception of light; the gait was staggering; there were no marked changes in sensation or in the reflexes; there was typical choked disk. A diagnosis of cerebellar tumor was made. Subsequently the man developed slight paresis of the left facial nerve with fibrillary twitchings of the muscles in this region, and the hearing on the left side became greatly impaired. In walking, the man deviated to the right. He died in December, and at the autopsy a tumor was found at the base of the left cerebellar hemisphere. It was a spindle cell sarcoma. This could have been enucleated had it been in a more accessible situation.

DR. SCHLAPP said that about a year ago he had presented to the New York Pathological Society a case similar to the one presented this evening by Dr. Hunt, showing degeneration of the spinal cord. The specimens from his case has been counterstained with acid rubin, and the sheath of Schwann was stained. In all of the cases the degeneration extended to this sheath, especially in the cranial nerves, the trigeminus, the glossopharyngeus and the vagus nerves. He had expressed the opinion at that time that the sheath of Schwann might have some protective influence. He did not think the case tended to disprove the toxic theory. There were no sensory symptoms in the beginning, and

probably the degeneration was at first confined to the fibers passing from the posterior columns into the gray matter. The poison appeared to be selective in its action, involving only the reflex fibers. The degeneration was particularly marked in the sensory nerves.

Dr. W. M. LESZYNSKY said that he had been interested in the fact that respiratory failure had preceded cardiac failure in Dr. Clark's case. One of his own patients had died upon the operating table just as a cerebellar abscess was reached. The heart continued to beat for eight or ten minutes after the failure of respiration. If degeneration existed in the posterior columns in the upper portions it must act chiefly on the third or fourth lumbar segments in order to produce loss of knee jerks; now, then, would one explain those cases in which the knee jerk was absent for a time, then became well marked, and was alternately present and absent?

MUSCLE TONUS AND TENDON PHENOMENA; THEIR RELATIONSHIP AND INTERPRETATION.

DRS. J. FRAENKEL and JOSEPH COLLINS presented this paper, which was read by Dr. Fraenkel. It was based upon tonometric examinations of two hundred and thirty patients. The authors stated that at the present day the view most generally held was that the tendon phenomena were expressions of muscle tonus. General clinical experience showed a definite relationship between tendon phenomena and the tonicity of muscles. Hypertonia, or exaggeration of the tendon jerks, was a symptom of disease of the pyramidal tracts. The tonometer used in this investigation was the invention of the house physician of the Montefiore Hospital. A total of 554 registrations had been made. The 230 cases were distributed as follows: apparently healthy, 32; cases of tabes, 25; of organic disease of the nervous system, 33; functional disease of the nervous system, 40; pulmonary disease, 70; heart disease, 12, and various other chronic affections, 18 cases. There were 71 registrations classed as hypertonia. It was found to be frequently, although not always, associated with exaggerated Achilles reflexes. Hypotonia was found to be frequently associated with loss or diminution of the tendon phenomena. There was a comparatively small number of neurogene hypotonias in proportion to the cases of general hypotonia. Neurogene hypotonia and absence of diminution of the tendon reflex were found frequently associated. Neurogene hypotonia with exaggeration of the tendon reflexes was present in 6%. It was concluded that hypotonia produced by damage of the ascending tracts of the spinal cord was accompanied by loss or absence of the tendon phenomena in every instance. In the cases of hypertonia absent or diminished reflexes were present in 6% of the registrations. In the cerebral group there was found a larger percentage of hypotonias than of hypertonias. In the spinal group 100% gave exaggerated tendon reflex and 95% showed hypertonia. It had been learned that whenever the neurogene tone was markedly increased or decreased the tendon jerks were increased or decreased correspondingly. The authors concluded that disease of the posterior tracts caused hypotonia, and dis-

ease of the pyramidal tracts caused hypertonia. There was a large group of cases giving normal tonicity and normal tendon phenomena.

Dr. G. L. WALTON of Boston said that in the exhaustive discussion on reflexes and tonus opened by Crocq in 1901 the reader had reviewed the clinical and experimental evidence which tended to show that the reflexes generally corresponded to the tonicity. The exceptions to this rule he explained as illustrations of the fact that the centers for tonicity (at the cortex) and those for the deep reflexes (in the basilar region) were separate. This explanation was not directly discussed, though the limitation of these functions to the regions indicated was seriously questioned. The readers tonight had reinforced in a most convincing way the results of Crocq, though their explanation of the exceptional cases differed from his materially. The question was too complicated to be discussed in its entirety, especially in the absence of exact knowledge as to the seat of either the tonus or the reflexes, but such work as had been reported this evening furnished one of the definite steps by which one might gradually mount to a knowledge of this complex subject. We had been so long imbued with the notion that in man, as in the frog, the spinal cord was the center for reflexes and tonus that it was difficult to transfer our study of these functions to the brain. Even in case of disturbed reflex in cerebral disease, we were still apt to think of the function of the brain as limited to the withdrawal, or the increase of influence upon the cord, through the pyramidal tract. For a long time the hypotonicity and loss of reflex sometimes found at the onset of cerebral hemorrhage were attributed to the shock conveyed to the cord. At the discussion already alluded to the disputants, while recognizing the importance of the cerebral influence, were by no means in accord with Crocq in limiting the reflex centers and the centers of tonicity to the brain. Dr. Walton said he had several times taken occasion to suggest that, instead of speaking of lower centers controlled, or inhibited, by higher centers, inhibited perhaps in their turn by still higher centers, we should recognize the combined action of all centers, cortical, basal and spinal, allotting to certain regions a predominating reflex function, liable to transference to a lower level on gradual withdrawal of upper level influence. According to this view, each reflex movement might be regarded as a resultant of the activity of various loops of different lengths, connected with each other both laterally and vertically. The more he had observed the reflexes in cerebral disease, the more he was inclined to accord the cortex the predominant rôle in the deep, as well as the superficial reflexes, and in the tonus. It was difficult, for example, to explain on any other basis the absence of deep and superficial reflexes in the following case: The patient was unconscious and hemiplegic, with a temperature of 105° F. and all reflexes absent up to the time of his death. The Kernig symptom was present, showing, probably, comparative hypertonicity of the hamstrings, but the extremities were otherwise obviously hypotonic. Autopsy showed pneumococcus meningitis of the convexity with encephalitic invasion of the cortex. In other cases of meningitis the reflexes were frequently preserved, but in one case of meningitis coming under his observation, in which

both brain and cord were affected, during the stage of rigidity and obvious hypertonicity, the reflexes were absent, but reappeared as relaxation set in, first on the side first relaxed. One must evidently look farther than to separation of the centers to explain such conflicting phenomena; in fact, different cases might require different explanations. Possibly it was partly a question of comparative tonicity. In the last case, for example, the hamstrings might have possessed hypertonicity so far in excess of the hypertonicity of the quadriceps femoris as to "snub" the knee jerk. In long standing infantile cerebral hemiplegia with contracture the deep reflexes were often absent, though hypertonicity was apparent. Doubtless in some of these cases the contracture was in such position as to put the tendons on too great or too little stretch, thus mechanically preventing the reflex. The combination of exaggerated reflexes with hypotonicity was sometimes seen in Erb's syphilis of the cord, especially in the early stages. In a recent conversation with Dr. Courtney, he had suggested that the affection about the fibers of the pyramidal tract was sufficient to impede the transmission of voluntary impulse and of tonicity from the cortex, but the reflex stimulus passed the more rapidly, as in neurasthenia, uninhibited by the volitional mechanism. Though not sure that he had thoroughly grasped the explanation of the readers on this point, Dr. Walton felt that they had proceeded along logical lines.

DR. C. L. DANA thought the authors had established quite clearly the relations of hypertonia to the reflexes, and had given to the neurological world tangible working data. He had not fully understood the explanation of the effect of the brain on hypotonus and hypertonus. Personally, he made use of a working hypothesis which fitted in very well with the explanation given in this paper. In all the sudden insults to the brain occasioned by hemorrhages producing profound hemiplegia, there was always absence of the deep reflexes on the paralyzed side, and with it no doubt hypotonia; whereas there was not this loss of reflexes on the non-paralyzed side. After a time this absence gave place to an increase of reflex. If, however, the hemorrhages were more posterior and involved the sensory sphere, there was more definite and more prolonged absence of reflexes.

DR. B. ONUF referred to a case in which a tumor of the hip and shoulder centers was diagnosed, and the tumor removed, with the result that a very marked hypotonia developed in the paralyzed extremity after the operation, and was present even two months afterward.

DR. COLLINS said that Dr. Fraenkel was satisfied with having established the relationship between tonus and reflexes, and they were both particularly gratified with Dr. Dana's statement that in his cases of cerebral hemiplegia he had observed that the farther posteriorly the lesion extended, either into the sensory cortex or the sensory representation of the capsule, so in proportion was the existence of hypertonia or the lateness with which it appeared. This clinical experience fortified very greatly the position taken in the paper.

DR. FRAENKEL said that he too had been delighted at the confirmation of their position by the very large clinical experience of Dr. Dana. If their ob-

servations were correct they should be of value in connection with diagnosis of true lesions of the pyramidal tract associated with hypertonia and of the posterior tract with hypotonia.

THE OBSTETRICAL SOCIETY OF BOSTON.

MALCOLM STORER, M.D., SECRETARY.

MEETING of Jan. 20, 1903, the President, Dr. G. J. Engelmann, in the chair.

DR. P. E. TRUESDALE of Fall River read, by invitation, a paper entitled,

CÆSARIAN SECTION FOR PLACENTA PREVIA, WITH REPORT OF A CASE.¹

DR. J. H. GIFFORD: I trust I may be pardoned for saying something that Dr. Truesdale's modesty will prevent him from saying, and this is that the fortunate result in this case is largely to be ascribed to the neatness and dispatch with which the operation was performed. This celerity is of especial importance in operations where there has been a great loss of blood. We have listened to-night to two papers that are apparently antagonistic. But it seems to me that this is so only because they look at the question from different points of view, from opposite sides of the shield, as it were. Version followed by slow delivery seems to me to apply more to cases in the earlier months, while Cæsarian section is more adapted to the later weeks of pregnancy. A Cæsarian section would not be indicated when the child is dead. Therefore the question of operation depends on what is most conducive to the welfare of the child. Now children, even if viable, are very likely not strong enough to live until the very last weeks of pregnancy, so that we must regard the Cæsarian section as applicable only to cases where the child is not only alive, but likely to live. I think the writer is right in giving greater value to child-life. In cities like Fall River more than half the population have this feeling very strongly, and the feeling is one that has a right to be respected. Of all the series of Cæsarian sections that I have seen reported, apart from that of Dr. Reynolds, the most interesting was one of such operations done upon themselves by savage women, where naturally no question as to length of incision or method of closing it arose, but where reliance was upon nature's antiseptics, with surprisingly good results. I beg to differ with the teaching that Cæsarian section is not an operation that should be done in private houses. With the modern ease of procuring trained nurses and sterile dressings, etc., such operations can be done with safety in ordinary homes.

DR. CHARLES M. GREEN: I wish to express my admiration of the care Dr. Truesdale has shown in collating his statistics, of his highly successful maternal result, and of his convincing presentation of his case. I am not yet convinced that Cæsarian section should be the operation of election in placenta previa, in the absence of indications other than misplaced placenta. However, there is much to be said on both sides of this question, and we ought to keep our minds open on this subject for further light. Of course there can be no object in

¹ See page 359 of the JOURNAL.

performing Cæsarian section for placenta previa prior to fetal viability, unless it can be shown conclusively that the mother's chance of recovery is thereby greatly improved. I am not yet convinced that such is the case. I cannot give my own statistics off hand, but I know that my percentage of maternal loss in cases delivered by podalic version has been very low.

When pregnancy has advanced to the later weeks before symptoms appear demanding delivery, when the fetus is alive and is likely to live, when the gravida is in good condition, or by reasonable delay can be brought into good condition, when, above all, she is a primigravida with not easily dilatable vagina and perineum, I am willing to grant that abdominal section may be very properly considered in the interest of the child. I sympathize with Dr. Gifford's remark that we ought to take into consideration the religious belief of the family. Personally, I always place fetal life, with its many uncertainties, as of secondary importance to maternal life. But both in my teaching and in my practice I feel it to be my duty to give to fetal life the first consideration, if such is the intelligent parental desire.

I must enter my protest against the Porro operation, if in any case it is decided to deliver by abdominal section. Very many women recover from placenta previa, and subsequently bear living children, and we have no right to remove the uterus, unless absolutely necessary to maternal safety.

DR. EDWARD REYNOLDS: I have done so much in advocating Cæsarian section for the sake of the child that I do not hesitate to take the opposite ground on this question. The danger to the mother in placenta previa is so great that that of the child should take a second place. Delivery by version in any but the most extreme collapse, with the ordinary soft cervix, is an operation of no great mortality in the hands of thoroughly skilled obstetricians. All depends upon the operator's boldness, skill and promptness. Thus the equation of the individual operator comes in very much. In the hands of men unskilled in version, yet skilled surgeons, a Cæsarian operation is doubtless the most likely to be successful, and, furthermore, should the man in charge of a case of placenta previa seek a consultant, a skillful surgeon is generally more easily reached than a skillful obstetrician.

One vital point that I have noticed in the discussion of this question is the fact that as post-partum hemorrhage comes largely from the dilated and partially paralyzed blood vessels of the cervix, there should be less hemorrhage after the removal of the placenta without the dilatation of the cervix by the passage of the child. For this reason I have no hesitation in saying that where the cervix will contract and still has its resiliency left I should do a Cæsarian section, I would avoid doing one if the cervix were partially dilated.

DR. F. S. NEWELL: My feeling is that except in pelvic conditions where a Cæsarian section is demanded anyway, or where, as is rarely the case, dilatation of the cervix is difficult or impossible, Cæsarian section is not demanded. The child has, however, rights of its own, and immediate delivery gives it a good chance if this first indication of placenta previa is met, that is to say, if the first hemor-

rhage is recognized. That is the most important part of the whole matter.

DR. J. G. BLAKE: No hard-and-fast rule can be laid down. The individual case must be considered. In his case Dr. Truesdale unquestionably saved his patient's life. She had already lost much blood, and probably would have lost much more with any other treatment. If a case is taken in time such an operation involves no great danger, but we must operate early before too much blood has been lost.

DR. H. T. SWAIN: The question when to operate by whatever method is a very important one. If we operate when the woman is in a state of collapse the chances are bad either way. Get your patient in a suitable condition first if possible. The investigation of the question of blood pressure may be of great importance in this connection. We must have some reliable statistics as to the blood pressure in pregnant women. We sometimes cannot control hemorrhage by packing and have to operate at once, but when we can control the hemorrhage many patients are lost by inopportune operations of one kind or the other.

DR. F. B. HARRINGTON: It has been of interest to me to see how much less opposition to Cæsarian section in certain cases has been shown in the discussion tonight than was the case when we talked the matter over some months ago. May I ask Dr. Higgins to define a little more exactly the cases that he at present feels are suitable for Cæsarian section?

DR. W. E. BOARDMAN: I would like to emphasize the interest of the child. It seems to me that Cæsarian section with modern technique ought to reduce the infant mortality very materially. This, however, can be brought about only by educating the public up to coming under observation before patients are in the bad condition in which we usually find them. Many years ago, I advocated, in opposition to the recognized teaching, that we should anticipate exhausted nature and deliver women when they are still in condition to withstand the shock. The popular mind has gradually come around to understand this. I speak of this as instancing how the popular mind can be educated.

DR. G. J. ENGELMANN: Dr. Truesdale has made an admirable argument for Cæsarian section. Perhaps I did not grasp just what class of cases he regards as applicable for the cutting operation. I trust I did not understand him rightly in advocating it for all cases of placenta previa. He has given us statistics making it appear that placenta previa is a desperate condition. He might have given us other statistics. I have come across other statistics. For instance, Lohmeier had himself ninety-three cases with only one death. This might be explained by his great skill, but in his clinic, where the cases were treated by his assistants, good and poor, there were one hundred and one cases with only seven deaths. Frye and Mann have had equally good statistics. In fourteen cases of Frye's, no mothers were lost and only three children that could be regarded as affected by the method of treatment. Good obstetricians have a low mortality. I have never done a Cæsarian section for this indication, being satisfied with my results treated by version and tamponnade of the cervix by a leg. If Cæsarian section is admissible it can only be in late

cases where the child is living and liable to live. Whether the os is dilatable or not is where the individual education comes in. I regard the Porro operation for this indication as being cruel, and one to be avoided.

DR. G. H. WASHBURN: I agree as to the advisability of Cæsarian section for certain selected cases of placenta previa, especially where there is a good chance of saving the child, but I have as yet never come across a case where it seemed indicated.

DR. CHARLES M. GREEN: I wish to say one word more as to the rigid cervix. I have never yet seen a case of placenta previa in the later months where the cervix has been rigid enough to cause any great difficulty; and this is especially true when the placenta is centrally planted. I once asked Dr. W. L. Richardson about this, and I think he would not object to my quoting him to the effect that he too has never seen a case. Such cervices are generally conspicuously easy to dilate.

DR. F. S. NEWELL: I have seen one case at full term where the dilation was very difficult.

DR. G. J. ENGELMANN: I think that the advocates of Cæsarian section should define their position very closely. I was once present at a discussion of this topic where a surgeon stated his opinion that in time Cæsarian section would be the school operation of placenta previa. I strongly oppose any such teaching as that.

DR. J. B. SWIFT: I would like to ask whether the fact of a woman being a primipara and having therefore presumably a rigid vagina should not have some influence on one's choice of an operation, out of regard for the child's chances.

DR. REYNOLDS: Dr. Swift has called attention to a very important point. We know how many tears of the soft parts occur in primipara in ordinary labors, if abnormally fast.

DR. SWIFT: Suppose then we have a primipara at full term with a placenta previa and the child viable, it seems to me that Cæsarian section is clearly indicated.

DR. HIGGINS: As to the child having greater chances after a Cæsarian section than after version, it seems to me that we have often seen children who were resuscitated with only the greatest difficulty after a Cæsarian section.

DR. REYNOLDS: Yes; but they were all resuscitated in the end. The explanation is probably that it is because having had none of the usual friction in coming down through the passages they need more than ordinary children after birth.

DR. SWIFT: This discussion has been very interesting to me, as it shows that much thought has been given to this question, and that some change of opinion has taken place since we considered the subject last year. I myself feel strongly in favor of Cæsarian section in certain cases.

DR. HIGGINS: I think the choice of method is largely a personal matter with each man. For myself, I would limit the Cæsarian sections to the small class of cases I have referred to. I think the indiscriminate advocacy of Cæsarian section for placenta previa will do much harm. In the majority of cases other operations are far better. I think Dr. Truesdale's paper is a very fair one. I do not think that the religious question should be allowed to be too prominent; my experience is that

parents do not care very much for the fetal mortality where the mother's life is at stake.

DR. P. E. TRUESDALE: I do not at all want to be put into the category of men who are radical enthusiasts for Cæsarian section. On the contrary I think the cases where it is indicated are very few. The statistics I quoted are from two sources, one a man radically in favor of Cæsarian section and the other as radically opposed to it. The one gave a maternal mortality of 25% with a fetal of 60, and the other gave a maternal of 7%. Another set of statistics of complete previa gave a maternal mortality of 18% and a fetal of 60 to 70%. At the Boston Lying-in Hospital the maternal mortality in complete cases was 24%, and these cases were handled by skilled men. At the Sloane Maternity the mortality in complete cases is about 20%. Here again the cases were treated by skilled hands.

I said that Cæsarian section is indicated in complete previa and in partial previa where a version cannot be done. I should like to modify this statement. Even when the placenta is centrally implanted I think it should be done only where the child is viable. An os that is dilated one half or two thirds will offer little more by Cæsarian section than by version.

In my case, though unfortunately the child did not live, the parents and friends expressed great satisfaction that it had been born alive and been baptized.

Recent Literature.

A System of Physiologic Therapeutics. Edited by SOLOMON SOLIS COHEN, A.M., M.D., Senior Assistant Professor of Clinical Medicine in Jefferson Medical College; Physician to the Jefferson Medical College Hospital and to the Philadelphia, Jewish and Rush Hospitals; one time Professor of Medicine and Therapeutics in the Philadelphia Polyclinic, etc. Volume V. "Prophylaxis," "Personal Hygiene," "Civic Hygiene," "Care of the Sick." By JOSEPH McFARLAND, M.D., Professor of Pathology, Medico-Chirurgical College, Philadelphia; HENRY LEFFMAN, M.D., Professor of Chemistry in the Woman's Medical College, Philadelphia; ALBERT ABRAMS, A.M., M.D. (University of Heidelberg), formerly Professor of Pathology, Cooper Medical College, San Francisco; and W. WAYNE BABCOCK, M.D., Lecturer on Pathology and Bacteriology, Medico-Chirurgical College, Philadelphia. pp. 539. Philadelphia: P. Blakiston's Son & Co. 1903.

The fifth volume of this system, containing "Prophylaxis," "Personal Hygiene," "Civic Hygiene" and "Care of the Sick," is a consideration of what forms practically an introduction to the science of medicine. In a manner not usual with systems of therapeutics, it discusses the development and spread of disease, and emphasizes well the importance of combining prophylaxis and treatment in teaching and practice. The chapters are well arranged, and they cover concisely yet fully a wide field. Each chapter is in a large measure complete in itself, and the book therefore becomes useful as one of reference.

A Treatise on the Diseases of the Anus, Rectum and Pelvic Colon. By JAMES P. TUTTLE, A.M., M.D. Illustrated. New York: D. Appleton & Co. 1902.

The author states that this book is practically the outcome of twelve years' experience in one of the first and largest clinics for the special teaching and treatment of rectal diseases.

It is a volume of 961 pages, which treats most fully of rectal diseases. The opening chapters describe the embryology and anatomy of the anus, rectum and colon with their environments, also briefly the physiology of the subject. Then follows a chapter on malformations. Next the technique of the examination of patients, under which head is described the methods of the examination of feces, which latter is more fully discussed than is usual in books of this special branch of surgery. Then in succession follow the chapters describing catarrhal diseases of this region, both acute and chronic; tuberculosis; venereal diseases; ulcerations; fissure in ano; abscess; fistulae; strictures; constipation; fecal impaction; pruritus ani; hemorrhoids; prolapsus recti; neoplasms, benign and malignant; operative procedures; foreign bodies; traumatism; and neuroses. The concluding chapter is devoted to a description of recto-colonic alimentation, a very important subject, in which the physiology of this form of nutrition and the details of its technique are discussed; after which two pages of formulæ for enemata are appended.

The book is fully illustrated with 338 well-executed cuts incorporated in the text in appropriate places, and 8 full-page colored plates.

Dr. Tuttle is a clinical teacher of wide experience, and his book possesses characteristics which will appeal to the student, the general practitioner and the specialist. He has formulated his method from personal observation of a large number of actual cases. He concludes therefrom that no one method always succeeds and that one must be conversant with many to be ready to meet all cases and emergencies. Therefore, while relating his own opinions and practices, he has tried to give those of other operators in order that his readers may have as complete a knowledge of the subject as possible. This broadens the character of the book and increases its value.

The volume is a complete review of the diseases of the anus, rectum and pelvic colon. It considers etiology, pathology, symptomatology, diagnosis and treatment. Modern methods and improved instruments for diagnosis are carefully described as well as illustrated.

The anatomical section in Chapter I is full and also effectively illustrated. It is well worth a careful study. Much space has been devoted to the physical examination of patients, to diagnosis and to details of local treatment. The non-operative treatment of each disease is first described with the class of case in which it will probably prove useful. Also where such measures are likely to be inefficient the writer has not hesitated to say so.

Operative treatment receives its full share of attention. Modern procedures and technique are described in detail, especially rectal extirpation, the more recent methods for severe cases of prolapse,

the treatment for colitis and colostomy. This portion of the book adds greatly to its value.

The 300 original illustrations are taken from actual clinical cases or dissections.

Dr. Tuttle states that his book has been written during an active practice, and that almost every opinion expressed therein has been actually tested. One can hardly demand a more practical test of the value of an opinion than he has himself already applied, except that furnished by the corroborating experience of his colleagues; evidence which in many instances is already at hand.

The book will undoubtedly soon be conspicuous in the actual "working" libraries of surgeons, physicians and rectal specialists, as representing this special field of medicine for to-day.

A Text-Book of Diseases of the Ear. For students and practitioners. By DR. ADAM POLITZER, Imperial-Royal Professor of Aural Therapeutics in the University of Vienna. Translated and edited by MILTON J. BALLIN, Ph.B., M.D., and CLARENCE L. HELLER, M.D. New (4th) edition, revised and enlarged. In one octavo volume of 896 pages with 346 original illustrations. Philadelphia and New York: Lea Brothers and Co. 1902.

This is the fourth edition of what may be called the most comprehensive treatise on diseases of the ear. It has been rewritten in parts, in order to bring the subject matter to date. The portion of the work dealing with sinus-thrombosis is an example of this, and it is gratifying to note that American surgeons are taking a prominent place as authorities on this subject, several being quoted in the text.

The various intra-tympanic operations are conservatively discussed by the author, and form a valuable record of the knowledge which has been gained in this field during the past few years.

Regarding the mastoid operation (p. 507), Politzer takes a stand at variance with nearly all American operators, contending that an opening into the antrum is unnecessary, and that it is quite sufficient in the great majority of cases to simply open the mastoid cells.

Much credit is due the translators for the able manner in which they have accomplished their task.

Quiz-Compend; No. 14. A Compend of Diseases of Children. Especially adapted for the Use of Medical Students. By MARCUS P. HATFIELD, A.M., M.D., Emeritus Professor of Diseases of Children, N. W. U. Medical School; Physician to Wesley Hospital, Home for Crippled Children, Chicago Orphan Asylum, etc. Third edition, thoroughly revised. With a colored plate. Philadelphia: P. Blakiston's Son & Co., 1012 Walnut Street. 1903.

This little book is even more unsatisfactory than most of its class. The classification is obsolete and irrational, and the subject matter antiquated. It is full of inaccurate statements and contains not a few misstatements. The treatment recommended is that of a generation ago rather than that usually employed today. The student who depends on this book for his knowledge can hardly hope to pass a modern examination in pediatrics.

Therapeutics of Infancy and Childhood. By A. JACOB, M.D., LL.D. Third edition. Philadelphia and London: J. B. Lippincott Co. 1903.

In these days of therapeutic nihilism it is refreshing, even if one does not fully share his enthusiasm, to find a man who still believes in the efficacy of drugs. While he emphasizes their usefulness, Dr. Jacobi nevertheless does not underestimate the value of diet, hygiene and nursing in the diseases of infancy and childhood, but attaches even more importance to them than to drugs. His advice and suggestions, based as they are on many years of experience and careful observation, are worthy of the most careful consideration by all who have to deal with these conditions.

The book is full of aphorisms, some of which compare favorably with those of Hippocrates. Some examples are: "The choice between a badly-tasting medicine and a fine-looking funeral ought not to be difficult." "It is useless to lose the patient while his disease is being cured." "There are, fortunately, practitioners who prefer making a diagnosis of the real condition of an ailing baby, and that and its improvement or cure comprise the main treatment I recommend for 'difficult dentition.'"

While we cannot agree with all of Dr. Jacobi's conclusions regarding the feeding of sick children, we cannot fail to admire the chapter dealing with this subject as a piece of controversial writing, and appreciate the skill with which he has made use of all the arguments favorable to his point of view and omitted those unfavorable.

Taken all in all, however, the book is a most valuable one and will well repay careful perusal.

The International Medical Annual. A year book of Treatment and Practitioner's Index. Twenty-first year. New York-Chicago: E. B. Treat & Co. 1903.

The Medical Annual, now in its twenty-first year, continues on the same plan inaugurated when its publication was begun, of condensing into a single volume a reflection of the medical knowledge of the year. The volume is so well known that notice need only be taken here that the principal change in the present issue is a general summary of the year's work, from which it is hoped that the general trend of opinion may be more quickly obtained.

Nephritis. Clinical Treatises on the Pathology and Therapy of Disorders of Metabolism and Nutrition. By PROF. DR. CARL VON NOORDEN, Physician-in-Chief to the City Hospital, Frankfurt-a.-M. Authorized American edition translated under the direction of BOARDMAN REED, M.D. New York: E. B. Treat & Company. 1903.

We are glad that Professor v. Noorden's monograph on nephritis has been translated into English. The original appealed to us so strongly that some months ago we gave our readers a summary of its contents. This is now referred to in lieu of a further review. Boston Med. and Surg. Journ., 1902, vol. cxlvii, p. 543.

E. P. J.

THE BOSTON

Medical and Surgical Journal

THURSDAY, APRIL 2, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (INCORPORATED),
283 WASHINGTON STREET, BOSTON, MASS.

THE THEORY AND PRACTICE OF MEDICINE.

It is an unending source of regret that we cannot rise above the conception that modern medicine is somehow irrevocably made up of two divisions which we speak of as theoretical and practical, or scientific and clinical. There is a certain very manifest tendency to exaggerate the supposed differences between these divisions and to minimize the relationships and interdependence of the one upon the other. As a matter of fact we shall never attain a broad-minded conception of medicine and its liberal teaching until we come to recognize the essential identity of the so-called theoretical or scientific and the practical or clinical sides. The exaggeration of differences which in reality do not exist and never have existed certainly stands in the way of the symmetrical development of our medical teaching and medical knowledge. The question of determining the character of a patient's pulse by touch or instruments of precision is precisely the same problem, viewed from a different standpoint, as the postmortem study of the arterial walls and physical condition of the circulatory apparatus. Both are eminently practical and equally scientific, if approached in the proper spirit of enquiry. To make a skillful physical examination is a scientific undertaking of the most difficult sort, altogether comparable with the subsequent study of the causes of the symptomatic manifestations during life. If we could only teach students and impress upon ourselves the undeniable fact that, petty distinctions aside, the problems of medicine are afforded by the cause, course and effects of disease taken as a whole, we should hear far less of "practical" and "theoretical," or of the more objectionable distinction of "clinical" and "scientific."

Whatever the future may bring forth, present tendencies are apparently not altogether encourag-

ing. A perfect reconciliation appears distant. The reasons are not far to seek. The so-called theoretical branches of medicine are being taught more thoroughly and in a more scientific spirit than ever before. Details of knowledge are, in a measure, giving place to insistence upon proper methods of study, and the supposed immediate needs of the practitioner have been more and more forced into the background of attention. An active agency in this direction has been the gradual steady exclusion of practitioners or of men holding hospital places from positions in theoretical departments, thereby still further removing, in the student's mind, the practical significance of their laboratory work. This combination of circumstances, together with the wholly justifiable eagerness of individual departments for the prosecution of original investigation, has led to a widening of the gap between the theory and practice of medicine, which all must regret. That the spirit of research should be encouraged to the last degree is self-evident; that the vitality of a medical school depends upon study into the most abstruse and apparently unpractical fields of medicine is absolutely unquestioned. Such lines of investigation cannot be carried too far, and every means should be applied to make such work effective. We are quite unwilling to admit that such an aim is antagonistic to the best interests of the future practitioner of medicine. It should on the contrary be a positive incentive to him, and conduce to a deeper comprehension of his ultimate work.

The fact remains, however, and it is a hard one to face, that there is an increasing tendency among students to neglect or ignore the relationship between the work of their earlier and later years. Anatomical facts, physiological principles and pathological details are a memory rather than a working basis of subsequent knowledge. The student during his first years is impressed with the importance of his laboratory study, as he should be, and during his later years he is too often led to believe this same study unpractical and unessential to his future success. To the physician looking upon the matter from the perspective of experience this may seem a matter of trivial import; to the student it means a state of confusion as to the meaning of his work, which is one of the most deplorable conditions in our present methods of instruction. That this is not a mere speculation must be evident to any one who has had an opportunity to teach the same students both in the theoretical and clinical parts of their course. The sense of connection is lost; the ability to integrate the knowledge already acquired with facts as seen in the clinic is not in evidence. No bridge has been provided from the

theoretical to the clinical aspects of the subject, hence, naturally enough, the student fails to see the connections which would be of the utmost service to him in his estimate of the condition under consideration. How often does a student apply his physiological knowledge to the most palpable facts of disease, or study his microscopic slides of pathological conditions in connection with his clinical work! No systematic attempt is made, ordinarily, to impress upon the student the fact that his antecedent knowledge of anatomy, physiology or pathology is never for a moment to be left out of consideration in his study of cases. Clinical and theoretical departments cannot be further separated if we are to maintain the coherence which is altogether desirable in a system of elementary medical education. Evidently some remedy must be found.

THE ELMIRA REFORMATORY.

THE New York State Reformatory at Elmira has long been an institution to which the public has looked for progressive methods of administration in the treatment of criminal and defective classes. The recent report for 1902 contains, in addition to many matters of general interest, certain details which appeal more particularly to the physician.

The manifest difficulty of treating successfully contagious diseases, among the most important of which tuberculosis must now be included, in public institutions of this character has long been recognized. The success which has attended the efforts at this reformatory are, therefore, quite worthy of attention. In speaking of this matter, Dr. Frank L. Christian, senior physician, considers the general subject under three heads: first, the care of the tuberculous person in the institution hospital; secondly, sending home all persons suffering with tuberculosis; third, the transfer of tuberculous patients to a properly equipped special hospital under the direction of the prison department. At Elmira the first method has been particularly resorted to, and it is felt not with altogether satisfactory results. In spite of precautions, complete isolation is impossible, and persons become infected through contact apparently far more readily than under other conditions. To send criminals home because they are suffering from tuberculosis is in many cases impossible, owing to their probable reversion to former habits of crime. The third suggestion is regarded as the most rational and the most likely to produce really satisfactory results. It is suggested that a common hospital be built to which prisoners suffering from tuberculosis in various parts of the State may be sent. Such a hospital has, however, not yet been attained.

It is interesting further, in looking over this report, to see how much attention is given to the details of medical treatment and to the study of the inmates as patients and as abnormal members of society. That much may be done to elucidate some of the most difficult and important social and medical problems at such institutions is unquestioned, and every encouragement should be given to those having charge of them to prosecute in a collective manner such researches. During the year 1902 but one death occurred from typhoid fever, and two only from pulmonary tuberculosis. The report further states the somewhat remarkable fact that out of a total of 1,523 men only a little more than 1½% are removed at one time from routine prison life by illness. When we compare this record with what happened in institutions of similar character several decades ago, we are again impressed with the progress which is being made in the prophylaxis of formerly fatal diseases.

THOUGHTLESSNESS OF HOSPITAL ASSISTANTS OR HOUSE OFFICERS.

IN talking with patients and their friends the hospital assistant or house officer sometimes forgets that, besides himself, there is usually another doctor in the case, to whom a thoughtless remark on his own part may do harm. Such criticisms as gave rise to the letter in the *JOURNAL* of March 19 are due, without doubt, to thoughtlessness rather than to any malicious design. But the necessity of remembering the "other man" (for tact often means merely a discreet silence) is such that the matter should not be passed unnoticed. We believe that too much may sometimes be said by clinical teachers in calling attention to examples of bad or unsuccessful treatment in order to impress a lesson on the student. The lesson, however, acts in two ways—it not only emphasizes the proper treatment, but it may lead the student to a thoughtless lack of consideration for an ill-trained or unlucky practitioner, whose difficulties and equipment he does not appreciate. Working under the direction of the best medical men in the community, the mistakes of other doctors often seem glaring to the assistant; his own mistakes are inconspicuous, or are shielded by the protecting wing of the institution where he makes them; perhaps, also, he has not lost a youthful overconfidence which may make him too ready to criticise others, or may sometimes, as described by our correspondent, lead him into an error of judgment worse than the one he finds fault with.

Hospital patients can rarely have at home the skilled care which they receive in the hospital wards, and the house officer is frequently impressed by

the work of men less favorably situated. Such cases, however, are by no means always the fault of the outside doctor; he has usually done the best he could do under the circumstances, and the house officer, with his better facilities, is on duty not only to treat the patient, but to deal thoughtfully when the occasion arises with a perhaps less fortunate practitioner. Above all, if criticism of treatment should be called for, let him be certain that he stands on firm ground.

MEDICAL NOTES.

THE MEDICAL CONGRESS AT MADRID.—In the interest of those who are going to attend the Fourteenth International Medical Congress at Madrid, April 23 to 30, it is announced by Dr. John H. Huddleston, secretary of the American Committee, that the French railroads have made their rate reductions for the members of the Congress depend on a special certificate, and on the use of the same route for going and returning. Any member of the Congress may, therefore, write immediately to the secretary-general at Madrid, stating at what port he expects to land and what route he will take. The secretary-general will send to him at the port named, under the address *poste restante*, the necessary certificate.

A MEMORIAL TO THE LATE PROFESSOR VON PETTENKOFER.—More than three thousand pounds have already been subscribed in Germany for the erection of a memorial to the late Professor von Pettenkofer in Munich. England has also interested herself in the cause, and contributions are being sent in to the committee appointed to co-operate with the Munich committee. The proposed memorial, it is said, will take the form of a monument.

TUBERCULAR HYDROCELE.—It is reported in the *British Medical Journal* for March 21, 1903, that a French observer, Jousset, has by a special method been able to demonstrate tubercle bacilli in the pale yellow serous fluid of ordinary hydroceles, which were clinically regarded as simple. In the hands of Tuffier, careful bacteriological examinations of such cases have for years given negative results, but it is possible that a new method will demonstrate the presence of bacilli in many of these simple cases, and lead to their being grouped with the other numerous forms of tuberculosis of serous membranes.

PROF. ENRICO BOTTINI.—It is announced that the distinguished surgeon Prof. Enrico Bottini of Pavia died March 11, at the age of sixty-five.

A PROPOSED LEPER COLONY IN THE WEST INDIES.—It has been reported that the Cuban Gov-

ernment has received proposals from a German scientific association, which is anxious to acquire the Isle of Pines for use as an international leper colony. Representatives of the association who have recently visited the Isle of Pines believe that the medicinal properties of the mineral springs are what they require, in connection with a salubrious climate, for a place of retreat for lepers of the civilized nations.

CORNELL'S ACCEPTANCE OF MR. CARNEGIE'S OFFER. — Mr. Carnegie's offer to defray the expense of the new filtration plant of Cornell University, at Ithaca, has been accepted. It is estimated that the plant will cost about \$150,000.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, April 1, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 33, scarlatina 29, typhoid fever 8, measles 31, smallpox 3.

BEQUEST TO SHARON SANITARIUM. — By the will of the late Mrs. Lucy R. Read of Boston the Sharon Sanitarium has recently received a bequest of \$5,000.

BEQUEST TO BOSTON MEDICAL LIBRARY. — Under the ruling of the Supreme Court of Massachusetts that the Boston Medical Library is a charitable institution, we understand that the library will be given \$50,000 from the Billings estate.

INSTITUTIONS CONFERENCE. — At the recent meeting of the heads of Boston municipal departments certain interesting facts and statistics were presented. The number of applicants for some variety of public care was in excess by 201 over last year, with a total of 4,321 for the year. The observation hospital at Deer Island received 287 persons, an increase of 87 over the previous year. Most of these were suffering from delirium tremens. Fewer dipsomaniacs were committed than in the previous year. Attention was drawn by the chairman of the pauper institutions trustees to the need of increased hospital accommodations at Long Island. The recently opened hospital for consumptives was fully occupied within two weeks, so that patients are now of necessity being cared for in the general wards of the hospital. That this is contrary to the best modern ideas is self-evident, and if patients with tuberculosis are to be sent to Long Island, the request is just that adequate provision should be made for their proper housing in separate wards.

DR. GRENFELL'S HOSPITALS. — It will be remembered that Dr. Grenfell has established five hospitals on the coast of Labrador and Newfoundland, which are used more by the natives and fishermen from New England than by men on board vessels of the British fleet which may be in that neighborhood. For the equipment of these hospitals many surgical instruments and much laboratory apparatus are required — in fact, almost any furniture fitted for a new mission hospital, especially such as could be used in a doctor's office, the matron's office, or a general convalescent room. Hospital supplies of any sort would also be welcome. It is hoped that, inasmuch as many patients treated come from New England, physicians and others interested will feel inclined to make liberal contributions toward the support of this worthy cause. The JOURNAL would be glad to furnish a more detailed list of special articles required to those who may be interested.

MEMORIAL MEETING FOR DR. JOHN HOMANS. — A memorial meeting for Dr. John Homans, under the auspices of the Boston Society for Medical Improvement, was held March 30 at the Boston Medical Library. Remarks were made by Dr. M. H. Richardson, Dr. A. T. Cabot, Dr. Geo. B. Shattuck, Dr. E. H. Bradford, Dr. R. T. Edes and Dr. S. W. Langmaid. The following resolutions were presented by Dr. J. Collins Warren and unanimously adopted:

Resolved, That we take this opportunity to express our appreciation of the prominent part which Dr. Homans has taken in the development of abdominal surgery, in his bold pioneer work in widening the field of this important department of modern surgery, and in placing it upon a rational and enduring basis;

That we recognize in his death the loss of a personality which has shed new luster on an already honored name, and has left a deep imprint upon the traditions of New England surgery.

NEW YORK.

APPOINTMENT. — Dr. Frederick H. Dillingham, assistant sanitary superintendent in the Health Department, has resigned, and Dr. Walter Benschel, who was a medical inspector, has been appointed to the position.

MALARIA AND TYPHOID IN THE HEALTH REPORT. — The condensed quarterly report of the Health Department for the last quarter of 1902, just issued, shows that there were 677 less deaths recorded, and a lowered death-rate of 1.21 points per thousand noted, as compared with the corresponding quarter of 1901. The one feature of this decrease standing out more prominently than any other, it is stated, was the number of deaths from the communicable diseases, all of which showed a considerable decrease, with one exception, typhoid fever, to which 44 more deaths were attributed

than in the last quarter of the year 1901; and if the decrease of 40 deaths from malarial fever be placed at the side of this increase, the question naturally arises, was this decrease in malarial fevers due to more accurate diagnoses, thereby placing these deaths among those of typhoid fever, or were the official and individual efforts aimed at the extermination of the plasmodium-conveying mosquito productive of such immediately beneficial results?

NEW BUILDING FOR LONG ISLAND COLLEGE HOSPITAL.—It is announced that through the generosity of J. Rogers Maxwell, the Long Island College Hospital in Brooklyn is to have a new building, replacing the one now occupied by it. Mr. Maxwell has offered to erect at his own expense the two central sections of the proposed structure as a memorial to his brother, Henry W. Maxwell, who for many years was a member of the Board of Regents of the institution, and who at the time of his death was engaged on a plan for its reconstruction. The whole will cost about \$1,000,000, and it is stated that George Foster Peabody and his two brothers have offered to defray the expense of equipping an operating amphitheater on the top floor of the Amity Street wing to accommodate 250 students. The hospital already possesses in its immediate vicinity the Hoagland Laboratory, erected by Dr. Cornelius N. Hoagland; the Polhemus Clinic, erected by Mrs. H. D. Polhemus as a memorial to her husband; and the Dudley Memorial, a home for nurses, the gift of Henry W. Maxwell in memory of Dr. William H. Dudley, one of the organizers of the German Central Dispensary, which afterwards became the Long Island College Hospital. The latter building has just been completed and handed over to the Board of Regents by Mr. Maxwell's executors.

REPORT OF STATE DEPARTMENT OF HEALTH.—In the annual report of the State Department of Health, which has just been presented to the governor, it is shown that there were 124,160 deaths in the State during the year 1902, a decrease of about 5,000 from the previous year. The death-rate was 17, which is the average for the five preceding years. The deaths from typhoid fever numbered 1,318, which is more than 300 less than the annual average for the past five years. There were 12,582 deaths from pulmonary tuberculosis, against an average of 13,270 for the five years. As a very general pollution of the water-courses and bodies of water throughout the state was believed to exist, the department undertook an inspection of a large number at widely separated points in the state, and secured evidence of the very general neglect to protect the purity of these various supplies. Immediate and general legisla-

tion which shall at least prevent an increase of these contaminations is regarded as a public necessity. To meet this a bill limiting or absolutely preventing the discharge of untreated sewage and other refuse or waste matters into the fresh waters of the State has been prepared and introduced into the legislature. Through the liberality of citizens of Buffalo, an excellent building has been erected for the cancer laboratory, and treatment of cancerous diseases has been steadily carried forward through the year. The work of the Antitoxin Laboratory, auspiciously inaugurated last year, has developed into very gratifying usefulness. The demands made upon the laboratory for diphtheria antitoxin especially have steadily increased, and this widespread distribution insures the prompt treatment of the proper cases, even if located in the most inaccessible parts of the state.

A FAITH CURE VICTORY.—The Appellate Division of the New York Supreme Court has reversed the verdict of the jury in the lower court, and ordered a new trial in the case of a faith curist of Mount Pleasant, Westchester County, who was convicted of failure to furnish medical aid to his two-year-old child, dying of catarrhal pneumonia, and who was fined \$500. In the opinion of the Court, which was written by Justice Bartlett, two other of the justices concurring, it was stated that, while the existence of a legal obligation to provide medical attendance was granted, it did not seem that such obligation applied in every case of illness in children, and in this particular instance the prosecution had failed to show that the illness was serious enough to render the failure to summon a physician a punishable offence. This faith-cure victory, therefore, is no great cause for rejoicing for Eddyites and others of their ilk, as it simply furnishes a needed lesson in the drawing of indictments. Justice Goodrich, one of the members of the court, wrote a dissenting opinion which contains an admirable statement of a principle which applies, or ought to apply, to all problems of this sort. "The doing of an act or the omitting to do an act," he said, "which endangers the life and health of a citizen, endangers the peace and safety of the state, and cannot be justified under the plea of liberty of conscience."

--- Miscellany.

TYPHOID PLASMA OBTAINED THROUGH THE USE OF LIQUID AIR.¹

In a communication to the Royal Society in August, 1902, Dr. Allan Macfadyen, director of the Jenner Institute, showed that the typhoid bacillus,

¹ Brit. Med. Journ., March 21, 1903.

when immersed in liquid air (about -190° C.) for as long as six months, underwent no impairment of vitality. The growth and functional activity of the organisms were unaffected, although there is reason to believe that intracellular metabolism must have completely ceased while the bacilli were in this solidly frozen state. Through other experiments, made by himself and Mr. Sydney Rowland, he was next led to the conclusion that the toxin of the bacilli was not extracellular but intracellular. The search for its intracellular origin was instituted in experiments somewhat as follows: The organisms were grown on ordinary beef-broth agar, and, after careful washing with distilled water, were disintegrated in a mechanical contrivance at the temperature of liquid air. In triturations with fine silver sand, as had been previously practiced, an appreciable amount of heat is evolved, by which chemical changes in the juice were obtained. The use of liquid air, however, insured that no chemical change took place during the disintegration, as well as that the organisms were disintegrated without the addition of any triturating substance. The disintegrated mass was now freed by centrifugalization from any whole bacilli or other suspended and soluble particles, and the resulting opalescent fluid was found on inoculation into animals in small doses to be invariably toxic or fatal. The conclusion, therefore, was arrived at that the typhoid bacillus contains an intracellular toxin. The cell juice thus obtained contained no living organisms, it could be easily handled, exactly standardized and measured into accurate doses.

The object which the experimenters had in view was to obtain from the bacillus the fresh unmodified cell plasma in its highest condition of physiological activity. As has been said, the trituration was originally performed with sand, and the plasma obtained by this method when injected subcutaneously or intraperitoneally in guinea pigs was found to confer complete immunity against a lethal dose of typhoid bacilli. The protection lasted for a period of about four weeks; it was also found that another immediate effect of the injection of the cell plasma was the appearance of the agglutination reaction in inoculated animals. The blood serum of rabbits which had received one injection of the cell plasma was found at the end of four weeks to have active, specific bacteriolytic properties as regards the typhoid bacillus. The blood serum caused the complete destruction of the typhoid bacilli when tested in the peritoneal cavity of a normal guinea pig. In the same way the blood of monkeys similarly treated exhibited similar agglutinated and bacteriolytic properties.

Lately Dr. Macfadyen has carried the matter somewhat further; he finds that by repeated injections of the immunizing substance obtained by the disintegration of the organism at the temperature of liquid air, the blood serum of the animal is rendered both antitoxic and bactericidal. Further, it was found that if an animal inoculated with a lethal dose of the living bacteria were, after half the time had elapsed necessary to bring about death, injected with the protective substance, it recovered. It would thus seem that the cell plasma prepared in this way holds out hope of affording us both the means of preventing and of treating typhoid fever.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MARCH 21, 1903.

| CITIES. | Population Estimated, 1903. | Reported deaths in each. | Deaths under five years. | Percentage of deaths from | | | | | |

Deaths reported, 3,710; under five years of age, 1,057; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 811, acute lung diseases 735, consumption 395, scarlet fever 37, whooping cough 49, cerebrospinal meningitis 14, smallpox 7, erysipelas 14, measles 50, typhoid fever 75, diarrheal diseases 82, diphtheria and croup 72.

From whooping cough, New York 14, Chicago 11, Philadelphia 4, Baltimore 1, Pittsburg 6, Providence 3, Boston 5, and Somerville, Brookton, Salem, Quincy and Revere 1 each. From erysipelas, New York 9, Chicago 2, Philadelphia 1, Baltimore 1, Boston 1. From smallpox, Chicago 2, Philadelphia 1, Pittsburg 4.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending March 7 the death-rate was 16.6. Deaths reported, 4,790; acute diseases of the respiratory organs (London) 251, whooping cough 112, diphtheria 77, measles 142, smallpox 16, scarlet fever 52.

The death-rate ranged from 6.3 in Handsworth to 26.5 in Coventry; London 16.4, West Ham 16.1, Brighton, 15.1, Portsmouth 15.5, Southampton 16.1, Plymouth 18.2, Bristol 16.9, Birmingham 17.8, Leicester 12.5, Nottingham 16.1, Bolton 19.5, Manchester 23.0, Salford 18.6, Bradford 18.2, Leeds 15.2, Hull 14.4, Newcastle-on-Tyne 22.1, Cardiff 13.9, Rhondda 16.1, Liverpool 20.1.

METEOROLOGICAL RECORD.

For the week ending March 21, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

| DATE | Barometer. | | Thermometer. | | Relative humidity. | | Direction of wind. | | Velocity of wind. | | Weather. | | Rainfall in inches. | |

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING MARCH 26, 1903.

STONER, G. W., surgeon. To proceed to Washington, D. C., for special temporary duty. March 20, 1903.

GODFREY, JOHN, surgeon. Department letter of Nov. 22, 1902, granting Surgeon Godfrey extension of leave of absence for three months, amended so that said extension shall be for two months and twenty-five days from Dec. 13, 1902. March 18, 1903.

MEAD, F. W., surgeon. Granted leave of absence for five days from April 13. March 25, 1903.

SMITH, A. C., passed assistant surgeon. Granted leave of absence for fifteen days from April 3. March 25, 1903.

ROBINSON, D. E., assistant surgeon. Granted leave of absence for two months and fifteen days from April 1. March 17, 1903.

SCHERESCHESKY, J. W., assistant surgeon. Granted leave of absence for one day. March 23, 1903.

GIBSON, R. H., pharmacist. Department letter of March 18, 1903, granting leave of absence for twenty-three days to Pharmacist R. H. Gibson, amended so that said leave shall be for eight days from March 9. March 20, 1903.

STIER, CARL, pharmacist. Granted leave of absence for one day, March 24, 1903, under paragraph 210 of the regulations.

PROMOTION.

Assistant Surgeon M. H. FOSTER commissioned as passed assistant surgeon, to rank as such from March 11, 1903.

CHANGES IN THE MEDICAL CORPS OF THE NAVY, FOR THE WEEK ENDING MARCH 28, 1903.

W. B. GROVE, passed assistant surgeon. Detached from treatment at the Naval Hospital, New York, and ordered to duty at the Naval Dispensary, Washington, D. C.

R. W. PLUMMER, passed assistant surgeon. Detached from the Navy Yard, New York, and granted sick leave for three months.

J. P. MURPHY, assistant surgeon. Detached from the "Glacier," and ordered to the "Monocacy."

RECENT DEATHS.

CHARLES FREDERICK PARKER, M.D., M.M.S.S., died at his home on Chambers Street, Boston, March 24, 1903, aged forty-three years. He had practised medicine in the West End for twenty years.

ROBERT SAFFORD NEWTON, M.D., of New York, a well-known neurologist and alienist, died on March 26 of cerebrospinal meningitis. He was born in Cincinnati, Ohio, in 1858, and received the degree of M.D. from the University of the State of New York. He was attending neurologist to the Presbyterian Hospital and to St. Mary's Hospital, Brooklyn.

CHARLES DICKENS EVANS BALL, M.D., M.M.S.S., died in Boston, March 29, 1903, aged forty-four years.

SOCIETY NOTICES.

BOSTON MEDICAL LIBRARY. MEDICAL MEETING.—The regular meeting will be held in the John Ware Hall, Medical Library Building, The Fenway, on Monday, April 6, 1903, at 8.15 P.M., sharp.

Program: Dr. Allen Greenwood, "Albuminuric Retinitis"; Dr. Franz Pfaff, "Some Remarks on Pharmacology and Therapeutics"; Dr. Charles Harrington, "The Therapeutic and Nutritive Value of Foods for the Sick"; Dr. Charles H. Williams, "The Need of Supplementary Lantern Tests for the Proper Examination of Color-Perception." Demonstration of a new Lantern.

ARTHUR K. STONE, M.D.,
Secretary.

543 Boylston Street.

AMERICAN ACADEMY OF MEDICINE.—The twenty-eighth annual meeting of the American Academy of Medicine will be held in the large Banquet Hall of the "Arlington," Washington, D. C., on Monday and Tuesday, May 11 and 12, 1903.

ALEX. R. CRAIG, M.D.,
Secretary.

MEETING OF THE BOARD OF MEDICAL EXAMINERS FOR THE STATE OF TEXAS.—The above meeting will be held in Austin, Texas, on April 20, 21, 22 and 23. Those who desire to take this examination must take out application, and present themselves not later than ten o'clock on the morning of the 20th of April at the hall for said examinations on the first floor of the Driskill Hotel Building, Austin, Texas. For further information or application blanks, address Dr. M. M. Smith, Secretary, Austin, Texas.

BOOKS AND PAMPHLETS RECEIVED.

Massage in Sprains, Bruises and Dislocations. By Douglas Graham, M.D. Reprint from third edition of "A Treatise on Massage."

Congenital Dislocation of the Hip. By Dexter D. Ashley, M.D., of New York. Reprint. 1902.

Experimental Research on the Heart of a Dog, with Reference to Cardiotomy and Cardiorrhaphy. By Benjamin Merrill Ricketts, Ph.B., M.D., of Cincinnati, Ohio. Reprint. 1902.

Heart Suture. By Merrill Ricketts, M.D., of Cincinnati, Ohio.

Cutaneous Blastomycosis. By James Nevins Hyde, A.M., M.D., and Frank Hugh Montgomery, M.D., of Chicago. Illustrated. Reprint. 1902.

Is the Adenoid Operation a Justifiable Surgical Procedure? By George L. Richards, M.D., of Fall River, Mass. Reprint. 1903.

The Use of Gelato-Glycerin Bougies in the Treatment of Acute Earache in Young Children. By George L. Richards, M.D., of Fall River, Mass. Reprint. 1903.

The Involution of the Appendix—Acute Suppurative Appendicitis as a Sequel thereto. By Horace Packard, M.D., and J. Emmons Briggs, M.D., of Boston. Reprint. 1902.

The American Year-Book of Medicine and Surgery, being a Yearly Digest of Scientific Progress and Authoritative Opinion in all Branches of Medicine and Surgery, Drawn from Journals, Monographs and Textbooks of the Leading American and Foreign Authors and Investigators. Collected and arranged with Critical Editorial Comments by various writers, under the general editorial charge of George M. Gould, M.D. Medicine. Illustrated. Philadelphia, New York and London: W. B. Saunders & Co. 1903.

Travaux du Laboratoire de Psychologie de la Clinique à la Salpêtrière. Profs. F. Raymond et Pierre Janet. Les Obsessions et la Psychasthénie. Paris: Félix Alcan. 1903.

The Diseases of Warm Countries: A Handbook for Medical Men. By Dr. B. Scheube. Translated from the German, by Pauline Falcke, with Addenda on Yellow Fever, by James Cantlie, M.B., F.R.C.S.; and on Malaria, by C. W. Daniels, M.B., M.R.C.S. Edited by James Cantlie, M.A., M.B., F.R.C.S., D.P.H. Second revised edition. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1903.

Conditions et Diagnostic du Terrain de la Tuberculose Pulmonaire. By MM. Albert Robin and Maurice Binet. Reprint. Paris. 1901.

Four Lectures on the Nature, Causes, and Treatment of Cardiac Pain. By Alexander Morrison, M.D., F.R.C.P. (Edin.) Reprint. London. 1902.

Fibroid versus Varix. By Daniel H. Craig, M.D., Boston, Mass. Reprint. 1900.

Pregnancy and Tuberculosis. Translated from the original MS. of M. Samuel Bernheim of Paris, by Daniel H. Craig, M.D., of Boston.

Character Study in the Examination of Persons for Military Service. By Franklin Bache Stephenson, A.M., M.D., A.A.S., Medical Inspector, U.S.N. Reprint. 1903.

DRY HOT AIR AS A THERAPEUTIC AGENT, WITH DEMONSTRATION OF THE BODY TREATMENT.¹

BY CLARENCE EDWARD SKINNER, M.D., LL.D., NEW HAVEN, CONN.

Professor of Thermotherapy and President of the Faculty at the New York School of Physical Therapeutics; Editor of the Department of Thermotherapy in the Journal of Advanced Therapeutics; Physician in charge of the Newhope Hot-Air Sanitarium, New Haven, Conn.; Member of the American Medical Association, American Electro-Therapeutic Association, American Roentgen Ray Society, American Association for the Advancement of Science, Yale Medical Alumni Association, etc.

Mr. President and Gentlemen — Dry hot air is but little known to the profession at large, hence in addressing a gathering of general practitioners it becomes necessary to treat the subject from a general rather than a technical standpoint. Like all new therapeutical measures, it has had to pass through an experimental stage during which its employment was purely empirical, and its place in the estimation of the masses of the profession was the unenviable though inevitable one occupied by all new measures the use of which is empirical.

Those of us who were sufficiently impressed by its early promises to continue the study of its remedial influences under varying pathological conditions, however, have become convinced that in it we possess an agent capable of exerting great power for good in many directions, and the result of this continued study has been the accumulation of data sufficient to rescue the employment of the measure from the mists of empiricism, and to place it today upon a firm basis of rational indication in a large number of diseased states.

The first question which logically comes up for consideration when a new therapeutical agent appears, is "How does it influence the human organism? What is its physiological action?" The question which *naturally* assumes the most attractive aspect, however, is "What will it do in a curative way?" and as in the case of the remedy under discussion the actual course of its therapeutical evolution was according to the *natural* rather than the *logical* order, we will, if you please, follow history, and first glance briefly at some of the clinical results producible and afterward consider the manner of their production.

Rheumatism was the first disease to the management of which hot air was applied, and it is in the treatment of this disorder that it has gained some of its greenest laurels. One of the most important points to be taken into consideration in judging of the efficiency of hot air, or any other element of treatment in this disease, is the very common error of diagnosticating as rheumatism conditions of an entirely different nature. Rheumatism has been made to bear a vast deal of undeserved opprobrium. At least three fourths of the cases which have come under my observation with this diagnosis have not been rheumatism at all, and, furthermore, many of them have involved the practical point of being disease processes which do not respond to anti-rheumatic therapeutics. True rheumatism, however, has been rescued by dry hot air from the category of diseases the treatment of which has long been

regarded as a reproach to the profession, and the affection can now be as satisfactorily and positively cured as any other disease, not excepting malaria.

It is always wise, and usually necessary, to give some salicyl compound with the hot air. This agent will always relieve the pain alone, and some cases are susceptible of cure with it alone, but the salicyl compounds with hot air effect a cure in nearly all cases, and I regard their administration as imperative.

Briefly, the results of the use of hot air in rheumatism are as follow:

First, immediate relief of pain, however severe, which relief may be rendered permanent by repeating the treatments as often as the pain becomes troublesome; every four hours, if necessary.

Second, shortening of the duration of the disease, which usually lasts only from five to ten days when hot air is thoroughly administered in combination with salicylic acid.

Third, lessening of the liability of cardiac involvement because of the rapid control obtained over the pathological condition, whereby the infection is inhibited from further attacks upon other tissues.

Fourth, the lessened number and quantity of the drugs which it is necessary for the patient to ingest, because of the increase produced in the efficiency and intensity of their action at the seat of infection; hence rendering it possible to avoid drug intoxication.

Fifth, in many cases which prove intractable to other measures its employment will render possible the extinction of the trouble.

Sixth, when properly and judiciously applied, its use is never productive of any vicious after-effect; on the contrary, the patient's general condition is immediately and greatly improved.

Sprains are often extremely resistant to the usual therapeutical methods, and recovery is not infrequently a matter of from six to eight weeks. When one of these injuries is brought under the influence of hot air, within four or five hours after it has been sustained all traces of the trouble will ordinarily have disappeared in from two to four days. Instead of weeks of painful confinement we have days only, and as the pain is relieved immediately the patient does not suffer. These two results of its application entitle hot air to a place in the first rank of remedial measures appropriate to this condition, if not to the first place. The effects of hot air in this situation appear magical at first sight to those who are not clinically familiar with the agent, yet they have been obtained by the speaker and others time after time within the last four years. The treatment may be applied as often as the pain shows evidence of returning, no matter how frequently, without any bad effect upon the patient. In this way he can be kept in a condition of constant comfort.

Arthritis deformans has been hitherto, under ordinary remedial measures, the despair of the medical profession. In hot air, however, we have an agent which alone will cure many of these cases, and which, in combination with static electricity and other rational therapeutical measures, will restore the majority of the victims of this disease to useful and comfortable lives. The pain is not so susceptible of immediate relief by dry hot air treatments

¹ Read before the Medical Society of the Borough of the Bronx, New York, N. Y., March 11, 1903.

as it is in rheumatism and sprains, but electricity, in the form of the static, faradic and high-frequency currents, supplements hot air very satisfactorily in this field. To secure the best results we ought to combine the other methods of physical therapeutics with hot air, a few drugs and dietary regulation.

The progress of the disease toward recovery is very slow, but usually fairly steady when estimated in periods of weeks. From six months to a year is the time usually required to produce a cure, although I have seen cases cured in a month; I have also had them require two years. In a disease so intractable to any treatment as this, however, it is a matter upon which we may most sincerely congratulate ourselves that we are at last in a position to promise the majority of our patients relief from their troubles; and this we may now safely do.

Pneumonia is another disease in which we frequently need all the therapeutical assistance that we can secure, and hot air is one of the most potent of agents in the treatment of this disease. A local treatment applied over the affected lung will relieve the pleuritis at once and remove all signs of consolidation in from two to five days. The patient begins to improve immediately after the first treatment, and, although the course of the disease is not shortened, the severity of its symptoms is very greatly decreased. This rapid removal of the exudate does away with the danger of heart failure from overdistention, and the getting rid of the pleurisy does away with a large proportion of the respiratory oppression and cough, whereby the patient's comfort is greatly increased. The happy influence of the body treatment upon the eliminative function will do more to relieve the profound systemic toxemia sometimes encountered than any other measure now known.

Local septic infection, proceeding from ordinary traumatism or surgical operation, responds most kindly to dry hot air. In the ordinary instances where the infection begins in a hand or foot, if the case comes under treatment before the infection has involved the lymphatics of the joint which connects the limb with the trunk, the local treatment will usually be entirely effective in producing a cure, and the patient will begin to improve after the first treatment. I have seen several cases of local infection, coming under treatment early, get well in three days. If the infection has gotten into the lymphatics of the trunk, however, the influence of the body hot air treatment upon the organism at large will have to be invoked. I have up to the present time treated fifteen cases of local sepsis, of different degrees of severity, and every one of them has recovered. If any structure has become so profoundly involved in the destructive process as to render regeneration impossible, suppuration will ensue as a matter of course, and surgical interference will become a necessity. Hot air will not remove pus. It will, however, in at least a majority of cases, secure the recovery of the patient either with or without surgical interference, and in so far it is of inestimable value in this condition.

The symptoms of chronic and acute nephritis are frequently very amenable to thermotherapy. The dropsy, oppression of breathing, mental somnolence, and cardiac disturbance of the acute exacerbations of the disease will sometimes diminish

during the first treatment and before the patient has left the apparatus. I have seen cases in which all the albumin had disappeared from the urine in three weeks, and as far as examination would show the patient had been restored to perfect health. How long this happy condition will continue it is of course at present impossible to say, but if the symptomatology does return the treatment can be applied again, and any nephritic would be glad if he could be maintained in apparent health by taking a course of hot-air treatments two or three times a year if necessary. The excretion of urea and the total output of urine are usually enormously augmented by the body treatment in this disease.

Lack of time forbids my discussing the other conditions in which hot air is useful at any length, and I will merely mention those in which it has been demonstrated to be of value, as follow:

| | |
|----------------------------------|--------------------------|
| Peritonitis, | Plumbism, |
| Pleuritis, | Lithemia, |
| Synovitis, | Varicose ulcers, |
| Nervous debility and exhaustion, | Neuralgias and myalgias, |
| Neuritis, | Alcoholism, |
| Tuberculosis of joints, | Muscular adhesions, |
| Fibrous ankylosis, | Osteomyelitis, |
| La grippe, | Periosteitis, |
| Typhoid fever, | Myositis, |
| Gouty diathesis, | Dysmenorrhea, |
| Atheroma, | Gangrene, |
| Syphilis, | Angina pectoris, |
| | Cholelithiasis. |

With these clinical results before us we will now, if you please, take up the physiological action of the agent, which when considered in connection with the pathological conditions obtaining in these different diseases will elucidate the *modus operandi* by which the curative phenomena are induced, and furnish us with a key to the rational indications for its therapeutical employment.

There are two varieties of hot air applications: one where only the part affected is treated, and which is denominated the "Local treatment"; and the other where the greater portion of the body surface is subjected to influence, and which is denominated the "General" or "Body treatment." The physiological actions of these two varieties of applications differ from each other in degree and to a certain extent also in kind, and we will consider first, if you please, the physiological influence of the local treatment.

This therapeutical measure affects physiological function in two ways: First, by a direct stimulation of cell metabolism in the part treated, due to the raising of its temperature *en masse*; and, second, by a reflex acceleration of cell nutrition set up by the stimulating influence of the heat upon the numerous nerve endings in the skin.

It is, of course, not possible to raise the temperature *en masse* of one portion of the body very much higher than that of another portion, but by placing the bulb of a clinical thermometer at the bottom of a deep sinus and then applying a hot air treatment, it has been demonstrated that an increase of several degrees Fahrenheit can be induced. This is enough to accelerate oxidation processes very perceptibly.

In diseases characterized by the presence of pathogenic micro-organisms in the part treated, as local septic infection and pneumonia, the inhibitive influence of this element of the physiological action

upon the growth and activity of the germs, whereby they are rendered more susceptible of attack by stimulated leucocytosis and cell metabolism, is very evident. It has been suggested that the germs in these cases were directly destroyed by the heat. This view, however, is improbable, and there is no experimental or clinical evidence available indicating that it is possible to raise the temperature of any portion of the body sufficiently high to produce this result.

Through the reflex influence is obtained an emphatic local hyperemia, which, together with the stimulation of the trophic nerve supply of the part treated, results in greatly increased local nutrition.

Copious perspiration appears upon the region treated, and in greater or less degree upon the rest of the body. The secretion is strongly impregnated with fatty acids whatever the disease from which the patient is suffering, or even if he has no disease at all. If a toxin is circulating in the blood, a certain amount of it will be eliminated with this secretion.

To these profound influences upon the circulatory functions of the part whereby stasis is relieved, is probably due the powerful influence of dry hot air treatments in relieving pain and swelling.

The general body temperature and pulse are but rarely much affected. Patients frequently exhibit an increase of a fraction of a degree in the former and eight or ten beats per minute in the latter, but nothing to influence the general metabolic functions markedly. That local hot air applications are sometimes capable of exerting profound reflex influence upon distant parts, however, was demonstrated in a case reported by Walsh. The patient had eczema of both hands; one only was subjected to the treatment, yet both got well. Cases also have been reported where pains in a limb on one side of the body have been relieved while the corresponding limb on the opposite side was being treated.

It will be observed that all of these effects tend to greatly increase the assimilation of remedies in the tissues subjected to their action.

The physiological action of the body treatment is predominantly reflex through the spinal sympathetic, the area of skin treated being so great that the capillary circulation is able to dissipate the heat before it penetrates deeply enough to exert its action directly to any great extent, herein differing from the local application.

Microscopical and chemical examinations, made in connection with patients under treatment by the writer, have demonstrated that the following phenomena are susceptible of immediate induction by the body hot air treatment.

First, if hyperleucocytosis is not already present, the number of white blood corpuscles is increased in different cases from 15 to 50%. If it is present, the increase is usually not so great, or it may be entirely *nil*.

Second, the red blood cells are increased from 10 to 20%.

Third, the quantity of urine passed in the twenty-four hours succeeding the treatment is usually increased from 25 to 100% over that passed in the twenty-four hours preceding. In a few instances, however, a decrease in the quantity has been observed.

Fourth, the quantity of urea excreted in the

twenty-four hours succeeding the treatment is increased from 15 to 60% over that excreted in the twenty-four hours previous.

These effects persist, with decreasing intensity, for from four to forty-eight hours and sometimes longer, the time varying in different diseases and with different patients.

It will be observed from the above that the beneficial effect of body hot air is not entirely due to the induction of hyperidrosis and superficial hyperemia, as is frequently stated, but that its influence involves phenomena of much greater profundity than would be explicable upon such an hypothesis.

When we consider the large number of pathological conditions in which the reconstructive functions are deficient, the modifications in the composition of the blood noted above assume an interesting significance; and when we think of the number and variety of diseases which are dependent wholly or in part upon the retention in the system of products of sub-oxidation, the sphere of action of the body hot air treatment, as indicated by its effect upon oxidation and the excretory function, becomes extended within limits of considerable magnitude.

The general phenomena induced by the body application are as follow:

The mouth temperature rises from 1 to 5° Fahrenheit, according to the length and intensity of the application and the susceptibility to stimulation of the individual patient's deep nerve centers.

The pulse is accelerated from thirty to fifty beats per minute, and is markedly increased in volume. If it was weak before treatment it now becomes strong. If the application is continued too long it loses its volume and strength, becoming rapid, small and soft, but sometimes retains its volume, becoming very soft and slow. Under these conditions the patient becomes dizzy, faint and nauseated.

The respiration deepens and the rate increases five to ten cycles per minute, but it is not accompanied by any oppression, — rather the reverse, in fact.

The capillary areas become injected, but this phenomenon is not so marked in the regions actually in contact with the heat as with the local treatment. The fact that the capillaries of the face, which is never subjected to the heat, share this general distention, even when constantly under the influence of the breeze from an electric fan, demonstrates the profundity of the reflex obtained.

The patient reeks with perspiration, the acidity of which is markedly increased over that normally exhibited.

The sensation is not disagreeable to the patient, but quite the reverse usually. A pleasant languor ensues after about ten minutes and lasts for an hour or two, and the patient usually becomes drowsy and sleeps. If the treatment is continued too long the languor gives place to exhaustion, with cardiac palpitation and oppressed breathing, which sometimes persist for hours.

By this profound stimulation of the deep trophic centers we secure a more rapid and complete oxidation of *effete* materials which are clogging metabolic processes, figuratively speaking, into normal excretory products, — urea for the kidneys, CO² for the lungs, etc., — which are then easily disposed of by the appropriate organs, and a rapid production of

more vigorous and healthier cell elements which are much better able than their predecessors to resist toxemia and microbic invasion. We not only obtain a corrective influence in nutritional disorders whose origin is in the deep sympathetic, but if the patient is suffering from an infectious invasion we increase vastly the resisting power of his phagocytes and tissue elements. The profuse perspiration carries out with it also a certain amount of any toxine that may be present, and thus assists in relieving the depression of nerve centers due to systemic toxemia.

The functional activity of every organ and tissue in the body is immediately augmented, but this exaltation of function is not followed by a reactionary debility. Patients frequently continue to improve generally, for months after a course of body hot air treatments.

It will be seen that the physiological action of hot air is in line with that of hydrotherapy, electricity, the Turkish bath and massage, but under some conditions is much more profound than any of them.

During the demonstration of the body hot air treatment which you are about to witness, you will be enabled to observe for yourselves the acceleration of the pulse rate and the modifications of the character of the impulse which have just been described, the rise in the body temperature, the profuse perspiration and the manifestation of deep reflex influence upon the sympathetic, as evidenced by flushing of the face, which will not be exposed to the heat.

In order to save time it may be as well to start the treatment now, and if you will approach the apparatus we will prepare the patient for the *séance*. As you will observe, he is wrapped in a Turkish toweling robe, boots made of the same material are drawn over his feet, several pillows are so placed under his body as to make his position comfortable while he is under treatment. We then place another thickness of ordinary Turkish toweling over that portion of his body which is to be exposed to the heat, and the preparation is complete. His pulse, you will notice, is 64 per minute and his mouth temperature 98.6° F.

The engineer informs me, I am sorry to say, that the total gas supply for this portion of the building comes through a half-inch pipe, hence we shall not be able to secure 350° of heat for this treatment. It is necessary to have at least a five-eighths inch supply pipe to secure this degree of heat in a body apparatus. We will do the best we can with what we have, however, and if the patient responds kindly it will be possible to demonstrate the phenomena susceptible of induction by the body application, even if the treatment intensity does not reach 350° F.

I had intended to have blood counts made upon the patient before and after treatment, in order to demonstrate the modifications produced, but Dr. Jeffries, who was to have rendered us this service, is unavoidably prevented from being present. I had also intended to have quantitative determinations made of the total urea output for the twenty-four hours preceding and again for a like period succeeding the treatment, but we have been obliged to substitute another patient for the one upon whom it was originally intended to demonstrate this treatment,

and through a misunderstanding a proper collection has not been made of this secretion, hence I shall have to ask you for the present to take my word for the fact that these modifications in blood and urine take place as I have stated.

In order that the degree of variation may be observed between the temperature of the air in the top of the apparatus, where the thermometer is ordinarily suspended, and that which actually comes in contact with the patient, I will suspend this second high-temperature thermometer through this ventilation aperture by means of this cord, at the level of the patient's body. We will now turn on the heat and leave the matter in charge of the assistant, while we finish our consideration of the subject, after which we will return and observe what modifications of the patient's physiological phenomena have been induced in the meanwhile.

I find the impression very prevalent among laymen, and to a large extent among physicians also, that dry hot air is lauded by its advocates as a panacea for all ills, to the exclusion of other remedial measures which have been demonstrated to be of value in diseased conditions. This impression is entirely erroneous, and the sooner it is removed the sooner will the thermotherapist be relieved from the undeserved opprobrium attaching to the false position in which it places him.

While it is unquestionably desirable to reduce our therapeutical armamentarium to its simplest form, yet it would not be desirable, wise or humane to withhold any useful agent from a suffering patient when the influence of that agent would prove beneficial to him. Valuable and numerous as have been the additions to our list of remedial agents during the past few years, yet we still frequently encounter cases which tax our resources to the utmost, and sometimes those in which our most strenuous efforts are inadequate for the securing of the patient's recovery. While the use of dry hot air renders the use of many of the older measures unnecessary, because under its application the indications for the employment of the older measures do not arise, yet when a rational indication exists for the administration of any other remedy it should by all means be heeded, and in many pathological conditions hot air *needs* to be supported by other measures in order that a satisfactory curative result may be obtained.

I have already stated the necessity of administering salicylic acid in rheumatism; in arthritis deformans it is usually necessary and always wise to combine dietary regulation, drug tonics and other methods of physical therapeutics with hot air; in pneumonia it would certainly be most illogical to withhold strychnia, nitro-glycerine, or any other adjunct, the administration of which was indicated; in local septic infection the knife should always be used when pus has formed or tissue is sloughing; in nephritis, he who would neglect dietary regulation and the administration of drugs, however well he may administer his hot air, will find that his clinical results will very frequently give him cause to wish for additional resources.

The key to the situation consists in bearing in mind that dry hot air is simply a rational therapeutical measure, exhibiting a known and constant physiological action, which gives us a rational basis upon which to consider its application to a given

case if the case in question presents a known pathology. It will, alone and unaided, cure some disease processes; others will require that additional therapeutical agents be combined with it; and in still others all the curative resources at our command will not suffice to effect the patient's recovery. It exhibits in a marked degree the capacity to increase greatly our power to overcome pathological conditions, and because of this and the profundity of its influence in many situations it is entitled to a prominent position in our armamentarium.

I will say just a word in reference to apparatus and technique. The local apparatus, to be effective, must be capable of producing a heat of at least 400° F. in twenty minutes, and of maintaining it steadily at that point as long as desired. The body apparatus should be capable of generating a heat of at least 350° F. in half an hour, and of maintaining it at that point indefinitely. The heat should equalize itself in all situations and localities inside the apparatus, so that the thermometer reading and the temperature of the air which actually comes in contact with the patient should not differ more than 10% of the thermometer reading. The simpler the construction of the machine the easier will be the attainment of this result.

The difference between proper and thorough technique and the reverse will very frequently constitute the difference between success and failure in clinical results, and in direct proportion to the prominence with which this fact is endowed in the mind of the prescriber of hot-air therapy will the benefit accruing to his patient be pronounced. Experience in the management of hot-air apparatus and a good knowledge of the clinical phenomena producible with it are very necessary. The current idea that it is a perfectly easy matter for any physician to secure a hot-air apparatus and treat his patient, without any special knowledge of the agent or of the technique involved in the management of it, with reference to different pathological conditions, is entirely erroneous and much to be deplored. When this unfortunate impression has been eliminated, which it is to be hoped will be in the near future, better results may be looked for from the general employment of the agent, and appreciation of its beneficent powers will succeed to the lack of confidence with which it is so frequently regarded at present. The bulk of its failures to accomplish results in the past have been due to a lack of proper knowledge of its clinical possibilities and physiological action, familiarity with which would have taught that the effects demanded should never have been expected of it, and because of inefficiency of the technique followed with reference to the individual case.

I wish to refer briefly to a popular criticism upon hot air, namely, that the curative results dependent upon its use are not *permanent*. This criticism is based upon the belief that hot air is only a palliative measure, like a dose of morphine in painful conditions, for instance, and would never be entertained if the profound influences upon physiological function, which we have been discussing, were taken into consideration. This belief was probably engendered by the observation that cases of rheumatism treated with hot air *alone* very frequently do "come back," but this merely means that the dis-

ease was not *cured* because the thermal agent was not properly supported, and neither hot air nor any other remedial agent can be expected to do alone what it will when combined with proper adjuncts. The advantages exhibited by hot air consist in its power to accomplish, either alone or in combination with other agents, that which it is impossible for any other combination of agents to accomplish without the aid of hot air.

Another fact bearing upon this criticism is that when we have carried a patient through an attack of pneumonia, typhoid, rheumatism or malaria, we cannot assure him that he will never have the disease again, no matter what curative agents we have employed. We can only be certain that this one attack has been extinguished. If appropriate environmental and constitutional conditions again obtain he will surely have to sustain another attack, no matter how perfect may have been his health in the meantime. When men no longer contend with conditions which engender habits of life that are inconsistent with their perfect physical health, then, and not till then, shall we be immune from repeated attacks of disease; and when that millennium has arrived hot air and every other remedial agent will have retired to the oblivion of complete *désuétude*.

In closing, I wish to refer briefly to another criticism which I have seen, namely, that local hot-air applications to localized infections of any sort were dangerous, and very likely to transform a local into a general pathological condition. I have never heard a logical defence of this statement, and I have never heard of an authentic case where there was any satisfactory evidence that such a result was properly attributable to hot air. Further, in the many thousands of such treatments which I have administered myself, and have had administered under my supervision to such cases, I have never, in a single instance, seen the slightest reason to consider that hot air had been guilty of precipitating such a disaster, and I am free to state my entire disbelief in the existence of any cause for apprehension in this respect.

We will now, if you please, return to the patient whom we left in the body hot-air apparatus, and observe what modifications, if any, have been induced in his physiological phenomena.

He has been under treatment thirty-five minutes, and the first thing that attracts our attention is the heavy perspiration and the marked dilatation of the capillary circulation of the face. When we left him at the beginning of the treatment his skin presented the dryness normal to that of a healthy man, now it is streaming with perspiration; before treatment his face was devoid of color except the slight rosy tint incident to a good circulation, now it exhibits a blush that would do credit to the modesty of a maiden of sixteen, should she find herself exposed to the gaze of so many representatives of the opposite sex in such a *déshabille* as invests the patient at this time. His pulse is 96 per minute as contrasted with 64 when the heat was turned on, and his body temperature, as registered by this thermometer which I have just removed from his mouth, is 100.6° F. as against 98.6° F. which you will remember was the previous reading.

We will now turn off the heat and allow the patient to cool, lying in the closed apparatus for ten min-

utes; then the ear will be drawn out and the patient left to cool in the air of the room for twenty minutes more. His temperature will by this time have returned to the normal and his pulse nearly or quite so, and he will be given a sponge bath with soap and water, to be followed by an alcohol rub. After resting in the recumbent position for an hour he will be in condition to get up and go home, and if any of you meet him during the next twenty-four hours it will be instructive for you to ask him how he feels.

The thermometer which was suspended in the apparatus registers 325° F. as contrasted with 335° F., which is the registration of the thermometer which is in the normal position, — a discrepancy of 10° F., which is, of course, not large enough to make any material difference with the efficiency of the treatment, and demonstrates that the apparatus which we have been using is reliable and efficient.

If any one has any questions to ask, it will give me great pleasure to respond to his queries.

THE RÔLE OF ATMOSPHERIC PRESSURE IN THE HIP JOINT.¹

BY SEABURY W. ALLEN, M.D., BOSTON,

Assistant in Anatomy, Harvard Medical School, Boston.

IN 1836 the experiments of the Brothers Weber went to show that air pressure played an important part in the mechanism of the hip joint; that when the joint was opened, the letting in of the air made it possible for the head of the femur and the acetabulum to separate; that on replacing the femur in its former position and covering the opening into the joint with the thumb, the then air-tight condition prevented the separation of the bones. Since this time most of the textbooks of anatomy, in successive editions, have made statements implying the truth of this, for example:

Cunningham, "Practical Anatomy," 1896, p. 252: "The cotyloid ligament fits closely upon the head of the femur, and, acting like a sucker, exercises an important influence in retaining it in place."

Gerrish, 1902, p. 243: "The cotyloid ligament, . . . aided by atmospheric pressure, holds it [the head of the femur] in place when its ligaments are divided."

Gray, 1901, p. 270: "The cotyloid ligament closely surrounds the head of the femur and assists in holding it in place, acting as a sort of valve."

Holden, "Osteology," 1887, p. 233: "When crusted with cartilage, the ball [of the femur's head] fits so accurately into its socket that it is retained by atmospheric pressure alone."

McLellan, "Regional Anatomy," 1892, p. 233: "The ligaments are considerably assisted by the atmospheric pressure, which is sufficient to hold the bones together after the severance of all the ligaments and of the overlying muscles."

Merkel-Henle, "Grundriss der Anatomie des Menschen," 1901, p. 132: "Lerade hier beim Huftgelenk ist der Luftdruck für die Integrität desselben von grosser Bedeutung."

Poirier et Charpy, "Traité d'Anatomie Humaine," 1899, vol. i, p. 728: "Evidement la pression atmosphérique intervient pour le maintien du contact entre

les surfaces articulaires, mais pas plus à la hanche qu'ailleurs."

Testut, "Traité d'Anatomie Humaine," 1899, vol. i, p. 576: "Parmis les causes qui maintenant les deux surfaces articulaires solidement appliquées l'une contre l'autre, la plus puissante est la pression atmosphérique."

Woolsey, "Applied Surgical Anatomy," 1902, p. 436: "The cotyloid ligament holds the head in place by atmospheric pressure, when the capsule and surrounding muscles are divided."

As it did not seem reasonable that the above statements could be true, the following experiments were made: Among sixty-four hips in the dissecting room there were found seven in which the bones fitted accurately together, and in which the muscles and ligaments had been sufficiently undissected not to interfere with careful data. The seven cadavers were suspended in the vertical position and three pins driven in, one into the anterior superior spine of the ilium, one into the iliac crest directly above the line of the thigh, and the third into the great trochanter of the femur. (Two points were taken on the ilium from which to measure, as it was thought that when the head of the bone fell out of the acetabulum it might do so in a direction parallel to the neck of the femur, — in which case the measurement from the anterior superior spine would be the most valuable; or it might do so directly downward, — in which case the measurement from the crest would be the most valuable.)

In the results, the average of these two measurements is given. In all seven cases, even after the suspension of the cadavers, the head of the femur was snugly in the socket, there being no appreciable separation of the bones, so that the conditions corresponded as closely to those in the living as is ever likely in the cadaver. Air was then let into the joint by trephining through the innominate bone from within the pelvis, and nicking the synovial membrane with scissors. In no case did careful measuring show the least separation of the bones. Therefore, whether air was or was not let into the joint made no difference in their relative positions.

If negative air pressure does not exist in the cadaver, it seems even less likely that it would be present in life, when the tonicity of the muscles and the elasticity of the ligaments are certain factors in maintaining the integrity of the joint.

To determine, then, what did hold the bones in contact, the muscles, capsular ligament and cotyloid ligament were successively cut, with the following result:

MEASUREMENTS IN CENTIMETERS.

S.T. Distance between anterior superior spine of ilium and great trochanter.
C.T. Distance between crest of ilium and great trochanter.

It would seem, therefore, that what holds the bones together is primarily the cotyloid and secondarily the capsular ligaments (of course in life the elasticity of the surrounding structures helping them out), and that "air pressure" need not be considered.

THE DOCTOR IN THE NAVY.

BY A. J. NUTE, B.S., M.D., WINTHROP, MASS.

ONE way of becoming a commissioned officer in the United States Navy from civil life is to be appointed a medical officer by the President.

It is interesting to know something of the history of naval surgeons. In early times he was before the mast, with small pay and the privileges of an ordinary seaman. Later he held rank similar to a warrant officer of today, and was classed as surgeon or surgeon's mate. At the present time in the navy he has no actual rank, but enters with the relative rank and pay, privileges, etc., of a lieutenant (junior grade), and through time may finally reach the relative rank of captain in the navy. One out of the entire corps may rank with a rear-admiral by being appointed surgeon-general through influence.

In order to enter, the candidate must be twenty-one years of age and a citizen; those are practically the only requirements for application. Application letters must be in candidate's handwriting addressed to the Secretary of the Navy, stating age, place of birth, residence, citizenship, a graduate or not in medicine, if so naming the school, and enclosing two certificates of character. The law does not require a candidate to be an M.D., although they usually get the preference.

Having mailed the above letter, he receives in return a letter of permission from the Secretary to appear before the examining board. This letter the candidate must mail to the chairman of the board, respectfully asking for a date on which to appear for examination. The board is in session from September 1st to July 1st at Washington, D. C. With the above letter to the board, it is advisable

for the candidate to send all the letters of reference, including both character and education, that he can get, especially from well-known people.

About a week later he will receive his letters back and an order to appear on a certain date, also naming the place and hour of examination in Washington. Examinations were formerly held at the Brooklyn Navy Yard, but last year the location was changed to a department building in Washington, in order to be a more central location.

On reporting at the time set, the candidate meets three surgeons constituting the board appointed by the surgeon-general, fully equipped to begin an examination that will last about ten days.

First comes the physical. The candidate must strip to the skin and be examined from head to foot for any signs of disease, and must also swear that as far as he knows he has no constitutional disease about him that can interfere with his duties. He is searched for any possible deformities, enlarged glands, veins, hernia of any part, condition of joints, skin, and a bad condition of any of the above mentioned is a cause for rejection. He is weighed, and his weight is required to equal two pounds to the inch in height. He is measured in height, and chest expansion, heart and lungs are thoroughly tested, also the hearing in each ear. Any peculiar marks or scars on the body are placed on record. The eyes also come in for a rigid but rather out-of-date form of examination. Each eye is tested in reading a printed card, and although the department allows glasses the vision must be perfect. The majority of college graduates of today require glasses for various defects of vision, and most of the foreign governments have not counted this against the candidate as long as it does not interfere with his work as a medical officer, especially in cases of uncomplicated near sight. There is good reason for this: the nearsighted man is never subject to eye strain, headache: as long as his work is within his visual field, he can work for many hours without any eye fatigue, and age tends to lengthen the vision. With the farsighted person that can usually pass the test, we find the whole condition reversed, and the man passed with far sight is worse off than the man rejected on account of near sight. This same condition also applies to the man suffering from certain kidney or constitutional diseases which do not show on the surface, as secretions are not usually examined, and the candidate may be in ignorance or not of the fact. Color tests are given, and then the mouth and throat are looked over.

If the physical examination has been satisfactory the candidate is then required to write a sketch of his past life in the form of a letter addressed to the board, including an outline of his school life, textbooks studied, and diplomas received. Having completed this, he is then asked to write a thesis on some subject assigned by the board, without reference to any notes or books, and must state what experience he has had in private or hospital practice. Then for ten days it is one continuous round of written and oral questions, not only in medicine but in every subject the board cares to ask about.

Usually it is carried on in the following detailed manner:

First day: Physical examination and letters of reference placed before the board.

Second day: Letter to the board describing candidate's life and education.

Tesis.

Three written questions in anatomy and physiology.

Third day: Oral examination in anatomy and physiology; number of questions not limited.

Three written questions in surgery.

Oral examination in surgery.

Fourth day: Three written questions in medicine, followed by an oral in medicine.

Fifth day: Eight surgical operations are usually done in a dissecting room, counts as practical surgery examination.

Sixth day: Pathology and microscopy; one written question in each.

Obstetrics and legal medicine; one written question in each.

Oral examination in above subjects.

Seventh day: Materia medica and action of drugs; two written questions followed by an oral quiz.

Chemistry and physics; three written questions followed by an oral.

Eighth day: Hygiene and quarantine; one written question in each followed by a series of oral questions.

Two patients are assigned to be reported on, one surgical, one medical when possible.

Recognition of instruments, cases of medical and surgical instruments are displayed, and candidate is required to name and describe the use of those asked for by the board.

Ninth day: Bandaging.

Use of microscope.

Examination in general subjects begun.

Tenth day: Examination concluded.

A general average of 75% must be obtained and in some subjects 80% and 85%, as shown in the official table below:

| | <i>Ques.</i> | <i>Required.</i> |
|----------------------------------|--------------|------------------|
| Anatomy and physiology | 2 | 80% |
| Surgery | 3 | 85% |
| Medicine | 3 | 85% |
| Pathology | 2 | 60% |
| Obstetrics | 2 | 60% |
| Materia medica | 2 | 80% |
| Chemistry and physics | 3 | 60% |
| Hygiene | 2 | 80% |
| General aptitude | | 80% |
| General education | | 80% |
| Total | | 750% |

These percentages are not absolute, and a loss in one branch may be made up in another, provided the above percentages in anatomy, physiology, medicine and surgery are obtained. General education covers grammar, arithmetic, geography, languages, history, general literature, elementary botany, geology and zoölogy. Aptitude is important, and can be enough cause for rejection. The look, bearing, ability and manner of the man as he comes in contact with the board is the basis on which the per cent is given. Oral examinations last from fifteen minutes to an hour, depending on the subject.

The board allows no part of the examination to be held elsewhere, and no allowance is made for

candidate's expense in taking the examination. A candidate may withdraw at any period of the examination with the consent of the board, and present himself at a later date. If, however, he fails to pass, he may be allowed a second trial a year later, but is not allowed a third.

Although the above is the general plan, the board have the power to conclude the examination at any time, or deviate from the above plan in any way that they think best for the service. If a man is disqualified in anything, there is such a thing known as obtaining a waiver, and he may be passed; this, however, requires influence. The board is under oath to report on the mental, physical, moral and professional qualifications of the candidate. If successful he is notified at once at the close of the examination.

Appointments are made as fast as vacancies occur, and in order of merit as reported by the board, but a qualified candidate not appointed within a year from date must take a second examination. For years back there have always been plenty of vacancies, anywhere from twenty to thirty at a time, but in the last year the vacancies have been filled and some acting appointments made as a waiting list. The question has often been asked as to what caused the lack of candidates. I think principally the examination, as it is rather peculiar, theoretical, and the system of the board makes it difficult, it tends to probe a man to see if there is something he does not know. The practical part of the examination is fair and in the reach of any good practical man, but that and the man's previous record has not counted as much as theory. Graduates of some of the smaller theoretical schools have always seemed to have the advantage in passing the test, and one advertised in a catalogue that about 20% of its graduates held commissions in the medical corps, also it has aided certain quiz schools that made a specialty in preparing young men for these examinations, and their circulars advertise success. The physical examination has also been a bar to many, especially vision, lungs and heart. There have always been plenty of men willing to try, but unless they could secure a waiver for a physical defect, it only meant rejection.

A man to be a military surgeon must be able to adapt himself to circumstances as he finds them, have the ability to make the best use of material that he has to work with if he gets caught in a tight place, and this requires practical men. The results of the navy system have not as yet been in actual test, as every shore station has direct communication with large civil hospitals for consultation, and on sea-going ships they have a picked body of men under their observation.

The war with Spain was not long enough to bring out the navy surgeon's value.

Now the young man having passed, he is ordered to procure an outfit of uniforms that cost about \$520, and report at the Navy Medical School at Washington for a six months' course of instruction in the duties of a medical officer, his place on board ship, naval etiquette, diseases peculiar to the service, and the various clerical returns and reports that he is supposed to fill out for record at the Bureau of Medicine and Surgery.

When the course is over he usually is ordered to

some ship or station. Usually orders are issued so as to give the surgeon from ten days to two weeks' time to make the necessary preparations. On arriving at the ship or station, he must dress in full-dress uniform with side arms, and report to the commandant, presenting his orders, and then he becomes an official part of the routine life. As stated above, he does not have positive rank, but is ranked as a staff officer, with rank relative to a corresponding grade in the line, so his uniform is made distinctive of his corps. The assistant surgeon wears the same general uniform as a lieutenant (junior grade), but has distinctive collar and cuff device. Where the line officer has a silver anchor embroidered on his collar the doctor has an acorn over a leaf, and the gold star on the line officer's sleeve is absent on the medical officer's, but in the latter case the gold cuff stripes are sewed on a maroon background. An assistant surgeon wears a stripe and a half on the cuff, the official stripe being one-half inch wide.

After serving three years as an assistant he is examined and if successful is made past assistant surgeon. When vacancies occur he is raised to the rank of a lieutenant, with the full two bars on his collar, two stripes on the cuff. Promotions continue in order of seniority, next being surgeon with rank of lieutenant-commander, giving him two stripes on the cuff and changing the silver bars to a gold leaf. The grade of surgeon is the last on which a regular physical and mental examination is required, promotions after that going in order of long service. The next rank is termed medical inspector, ranks with commander, three stripes on cuff, a silver leaf on collar and an embroidered visor on cap. The final rank is medical director, rank of captain, a silver spread eagle on collar, and four stripes on cuff.

The highest rank to be obtained is surgeon-general, with the pay and privileges of a rear-admiral. This appointment is made directly by the President, the term of office to last four years; therefore the position is usually given to some officer that will retire at the close of his tenure, as that retires him with the rank, etc., of rear-admiral. If a younger man was given the office, he would have to resume his original rank at the close of his term, unless the new President would re-appoint him, which would hardly be likely, as the position is much sought for. There are three important factors in making such an appointment: A man about to retire would never have to step back into a subordinate position, which might otherwise prevent him from doing his work independently; he retains the relative rank of rear-admiral for life, and the pay on the retired list is greater than he could ever get again, being some \$4,125 a year for life.

The life of a surgeon is easy, work is light, hours short and Uncle Sam is an excellent provider. Each officer is supplied with all the latest medical papers, instruments, books, chemicals and all kinds of laboratory apparatus free of cost. When traveling under orders he is allowed eight cents a mile, and many railroads make a reduced rate for officers so traveling, hence a trip from New York to San Francisco would net a tidy little sum.

The pay is first class; an officer perhaps never would get wealthy on it, but he always has a comfortable income and far more than he would obtain in civil life for the same amount of work, and at the

age of sixty-two he retires on three fourths of his highest sea pay, thus being furnished a comfortable income for the rest of his life. Sometimes complaints are heard from officers about their pay, but if the United States was to offer one half the entrance salary, they would have all the men they wanted and as competent surgeons. In Europe the young officers receive a much smaller salary, and among them Uncle Sam is noted for his liberal pay table.

An assistant surgeon at sea, on a receiving ship, or in colonies like Porto Rico, receives \$1,650 per year, with \$9 per month for ration allowance; on shore duty he receives \$1,402.50 per year and partially furnished quarters — ice, light, heat, messenger and laborer service. Junior surgeons have quarters usually in a hospital, while the senior has a fine large house to himself. Past assistants receive after five years at sea in the service \$1,800, on shore \$1,530; after five years with the rank of lieutenant, at sea \$2,160, on shore \$1,836. Surgeons receive from \$2,360 to \$2,520 at sea, and \$1,989 to \$2,142 on shore, with a time service of fifteen years. A surgeon's maximum pay is \$3,500 at sea, and \$2,975 on shore. Medical inspectors receive \$4,100 at sea, \$3,400 on shore. Surgeon-general receives \$5,500 per year afloat and ashore, but his duties are at the department unless he goes to sea on a tour of inspection. When officers are ordered to shore stations where no quarters are provided, they are allowed according to their rank from \$288 to \$720 per year added to their pay for rental of quarters.

They have on sea duty \$9 a month allowance as ration money, and for longevity pay receive an increase of 10% of their salary for each five years' service, until the total amounts to 40% increase; also they are allowed what they can make in private practice, and this often amounts to considerable in certain stations.

Social life is more or less a large factor in the life and makes quite a bill of expense, yet it is not always necessary, and if the surgeon does not care for it he can readily drop most of it and enjoy himself as he pleases. The greatest expense is food and clothing. Uniforms must be of good quality, and are expensive, but if taken care of last a long time. On board ship the food arrangement is known as the "mess," and each officer is charged an equal share in paying for it. One of the officers is elected caterer each month, and he makes out the bill of fare, collects the money and pays the bills. The cost of a mess is usually about a dollar per day to the man. Wine lists and cigars are furnished, but each individual pays for what he orders, so there is no question of any unfairness in the methods, and the man that does not care for extras does not pay for any others. On shore he must provide his own food and is supposed to pay his own servants, for at sea Uncle Sam provides cook, steward and mess-boy or waiter.

Medical officers spend three years at sea, then three on shore, and are allowed one month leave a year. This is not adhered to, as the needs of the service often demand sudden changes of station. Medical directors usually do no sea duty, but are placed on boards, or in charge of hospitals. In case of disability occurring in line of duty — and it is rare to find a record of any disability not duty, although the retired officer may be doing a busy prac-

tice outside — the surgeon retires to private life on three fourths of his present sea pay.

Duties on ship are light, as the men are all selected before being sent on board, so that all report on first-class order, and the mode of military life tends to keep them so. Sick calls in morning are practically his office hours, and he has the assistance of a well-trained apothecary with several apprentices. The apothecary does the clerical work and tends the minor cases besides the prescription work. On shore he has in addition the families of officers and enlisted men to attend. This increases his work but little, as most of the families have a civilian physician.

For illustration take a tour of duty at a New England station like the well-located and historical old Navy Yard at Kittery, Me. There the senior has a fine house, furnished, electric lights, heat and ice free, beautiful large lawns, fine vegetable and flower garden, all kept in order practically at the expense of the department; a man to do his errands and chores, a fine dispensary building within a few moments' walk of his house, fitted with as good an office and library as a doctor could wish. The dispensary is in charge of an energetic, well-educated pharmacist. The pharmacist has a well-arranged set of quarters on the second floor of the dispensary. Also under the senior is a well-furnished hospital, under direct charge of a junior surgeon assisted by one or two apothecaries and three apprentices. The naval hospital has an excellent location on the bank of the Piscataqua River, surrounded with broad lawns and plenty of fresh air and sunlight.

At that station the work is light, as it is a healthy location. Sick call sounds at 9.45 A.M., usually lasts less than an hour, then outside of a little official correspondence the senior's day's work is practically over, as the pharmacist takes care of the routine work in the way of making out requisitions, inventories and various daily and quarterly sick reports. Of course all stations are not alike, some have more work, others less, but as a rule it runs along in the manner above described.

If an officer is ambitious there are plenty of chances to keep busy. Research, sanitary and diet problems are always being brought up which the department heartily approves, furnishes everything to work with, and only asks in return that reports shall be made from time to time on the progress of investigation.

On a whole the life is such that it offers a great inducement, especially if one cares for institution life. It means a good living, good social position, comfortable income, travel, and retirement at the age of sixty-two from care and worry for the rest of one's life. The disadvantages are military system, which is necessary but never makes the officer independent, and service legislation with its political background. This latter is felt more than seen, but once in a while it crops out.

There are some disagreeable duties and stations, but they are few, and the department gives due credit for men doing such duties or serving on such stations. As far as the good and bad sides are concerned, a great deal depends on the man. He can loaf and take life easily as possible, his greatest worry being the next examination for promotion, and thus become useless as a medical man, and routine life seems to produce that effect on some. On the other hand

he can go ahead with an endless field to work in and carry on experiments that the outside physician in the ordinary walk of life could not afford the time and money to undertake.

Clothing is one of the largest bills to the young officer, as he needs an outfit of good quality, enumerated as follows: Special full dress, full dress, several working uniforms in blue, chapeau, shoulder knots, shoulder straps, at least six white uniforms, white cap frame with dozen covers, two blue fatigue caps, boat cape, overcoat, white shoes, sword and belt, rain clothes, heavy and light regulation gloves, and on going to sea must be supplied with a large amount of laundry.

The navy is like one big family, and the candidate once admitted finds a cordial reception, but as a stranger trying to enter he need not be astonished at a cold reception. There seems to be a feeling in the service that the ordinary citizen is an outsider instead of an employer, and the navy is a little social world in itself, the ticket of entrance to it being an appointment to Annapolis or a commission. In the service lines are drawn as sharply as in any European monarchy, and a high official would never think of inviting an officer of the grade of gunner, boatswain, etc., yet one is just as much of an officer as the other, and recognized by the official register as such.

The only difference seems to be the fact that the gunners, carpenters, pharmacists worked their way up and the lieutenant was appointed; but in social life that makes a great difference.

New Instruments.

A NEW MODIFICATION OF TARNIER'S AXIS TRACTION-RODS.

BY L. V. FRIEDMAN, M.D., BOSTON,

Assistant in Obstetrics, Harvard University; Third Assistant Visiting Physician for Diseases of Women, Boston City Hospital; Physician to Out-Patients, Boston Lying-in Hospital.

SOME apology seems necessary for further addition to the numerous existing traction-rods. I have had trouble with the instruments commonly used at present, and have learned that other obstetricians have had the same difficulty. The advantageous points of the rods here described have been used before, but no attempt has been made to apply them to forceps with the English lock, for which there is here so marked a preference.

The two types of traction-rods used here today are (1) Felsenreich's or Lusk's, and (2) Reynolds' or Higgins' modification of Tarnier's instrument.

The faults of the first type are of an obvious mechanical nature. The instrument can be applied only to forceps bearing a French lock; it has a bar so complicated as to render its attachment difficult, and it is essentially not a clean surgical instrument.

The second type is simple, clean and can be applied to any forceps; but in spite of the mechanical contrivance, the rods occasionally slip out. Constant attention is necessary to keep the rods in place during the application, and in swinging the rods into apposition, the good application — frequently attained with difficulty in high operations — is usually disturbed.

I have sought to combine the best mechanical features of both types above noted, and to produce a thoroughly clean instrument which could be applied to any forceps bearing an English lock. Numerous trials on the manikin and living patient lead me to think I have succeeded. I feel certain that the most important qualification, efficient traction in the axis of the pelvis, remains unimpaired. It is obvious that this cannot be made subordinate to minor mechanical advantages.

The following advantages are claimed for these rods:

During application the rods, being fast to the blades, require no attention. The blades being in position, the lower ends of the rods are readily sprung loose from the shanks, and the traction-hooks attached without disturbing the position of the blades. The rods follow the curve of the shanks of the forceps, therefore they do not strike the perineum suddenly with their extreme width, and consequently are less apt to rupture it. The instrument has but one closed joint, and here a new, clean joint has been devised to replace the usual screw. Every part of the device is adapted for thorough surgical cleanliness.

DESCRIPTION. (See cut.)

The instrument is made of crucible steel, hand forged. The rods attached by Higgins' modification (a) are short; when in place they do not reach the lock. They follow the curve of, and lie flat on, the under surface of the shanks. It is this inward curve (b) which is mentioned above as a protection to the perineum. During application each rod is held fast to the shank by a small pin (c). At the lower end of each rod is an oval eyelet (d) to receive the hooks of the handle. The bar is similar to those now in use, but at (e) it holds by a lock joint, instead of a screw, the curved upright which bears the hooks.

Fig. 1 shows the instrument in position for traction. Fig. 2 shows the side view in better detail.

The instrument is made by Codman & Shurtleff, Boston.

Clinical Department.

DEATH FROM A SINGLE VAGINAL DOUCHE. REPORT OF TWO CASES.¹

BY G. DE N. HOUGH, NEW BEDFORD, MASS.

CASE I. Mrs. J., aged thirty-three. On Monday, March 10, this woman, who was between three and four months pregnant, miscarried. The next morn-

ing she was given a douche of 1 to 1,000 corrosive sublimate, one quart. There is some doubt as to whether she received any more douches. On Thursday, March 13, her tongue was greatly swollen, mouth extremely sore, she was salivated and had a severe diarrhea. The whole mucous lining of the mouth became gangrenous, and towards the end of her life, the sloughs having separated, quite profuse hemorrhage took place. Diarrhea continued, apparently but little influenced by medication, and she finally died of exhaustion on March 26, fifteen days after receiving the douche. The autopsy showed numerous small ulcers in the ascending and descending colon; kidneys half as large again as normal; the uterus contained a soft adherent spherical mass, as large as half a hen's egg, which appeared to be a placental fragment, and which was proved to be such by microscopical examination.

The microscopical examination confirmed the naked eye diagnosis — ulcerative stomatitis, ulcerative colitis and acute parenchymatous nephritis. The bichloride douche was given by her grandmother, an old negro nurse thoroughly accustomed to administering douches, who was, at the time that I talked with her, not absolutely certain but was strongly of the opinion that she had given the girl but the one douche.

CASE II. Mrs. S., aged thirty-five. Sarcoma of the uterus.

Vaginal hysterectomy was performed on April 3, 1902. The patient was in poor general condition before as well as after the operation. On April 6 the vaginal gauze was removed, and a douche of peroxide of hydrogen was given. The following day the packing of the vagino-peritoneal wound was removed, and a douche of a dilute formalin solution was given. It was impossible to ascertain the exact strength of this solution. It may have been as strong as 1 to 1,000, or it may have been as weak as 1 to 5,000. This douche caused the patient severe pain, and soon after it was given she passed into a condition of collapse, and in spite of vigorous stimulation died in a few hours.

A careful autopsy was performed, and absolutely nothing was found to account for the death. I believe that the irritant action of the formalin on the peritoneal surface (there can be no doubt that the formalin solution penetrated to the peritoneal cavity) caused the pain, and pain so severe that the patient, in her weak condition, was thrown into the condition of shock, from which she died.

NOTES FROM THE NEUROLOGICAL DEPARTMENT, MASSACHUSETTS GENERAL HOSPITAL.

THE RELATIVE FREQUENCY OF MULTIPLE SCLEROSIS.

BY E. W. TAYLOR, M.D., AND J. W. MYER, BOSTON.

THE relative frequency of the occurrence of disseminated sclerosis in this country and in certain portions of Europe has been the subject of recent investigation. The apparent infrequency of the disease in America has been recognized for a considerable time. In the edition of his "Text Book of Nervous Diseases," published in 1892, Dana comments on its rarity, and makes the statement that but two cases confirmed by autopsy had been

¹ Report to Massachusetts Medico-Legal Society, Feb. 4, 1903.

reported in the United States up to that time. This statement is omitted from the later editions of the book, but during the intervening ten years very few pathological studies of the condition have been published in America.

Statistical investigations of much interest have been made within a year regarding the absolute and relative frequency of the disease. The question was discussed at a meeting of the New York Neurological Society, held Feb. 4, 1902,¹ at which a number of the leading neurologists gave their experience. Dana found that among 3,000 private cases there were ten cases of multiple sclerosis, and of 600 out-patients there were but two cases, and these were doubtful. At Bellevue Hospital among 12,000 patients (not alone with diseases of the nervous system) annually received, there were only one or two cases of multiple sclerosis each year. From these figures he was led to regard the disease as rarer here than abroad. Hammond reported that of 10,000 private and dispensary cases 47 had multiple sclerosis. Of 10,056 cases in Starr's clinic, 27 were recorded as multiple sclerosis, but in six of these the diagnosis was doubtful. Sachs found thirteen undoubted cases and two doubtful ones among 2,000 private cases, and was of the opinion that we had a faulty idea of the relative frequency of the disease in Europe and America. Onuf had made a positive diagnosis of multiple sclerosis in eight cases out of 500 to 600. Fisher reported eight cases out of 2,451. In 6,000 cases of nervous disease, Collins had seen 19 cases of multiple sclerosis. He regarded the disease as very rare. Fraenkel had diagnosticated multiple sclerosis eighteen times out of 1,500 patients observed at a hospital for chronic disease.

Taking the sevarious sources together, it appears that out of a total of 35,107 cases the diagnosis of multiple sclerosis was made approximately 234 times. The relative proportion of cases of multiple sclerosis would be considerably less if the figures submitted by Onuf and Fraenkel from hospitals for chronic disease were excluded.

Dr. Byrom Bramwell of Edinburgh has very recently collected statistics² bearing on the subject from his hospital and private practice, in which a very striking discrepancy with the figures we have quoted is shown. Of 5,825 cases of organic and functional nervous disease there were 100 cases of disseminated sclerosis. In comparing hospital patients with out-patients he found a much larger proportion in the ward cases, one in nineteen, as compared with one in 168 of the out-patient cases. This would be expected, and corresponds in a measure to Onuf's and Fraenkel's statistics to which we have referred. Bramwell is of the opinion that his figures underestimate rather than overestimate the actual number of cases. Excluding certain doubtful cases, he finally concludes that the proportion of cases of multiple sclerosis to the total number of cases of nervous disease in his practice is one to 82, as contrasted with the proportion of one to 219 in America, as he interprets the figures which we have in part quoted. The discrepancy is certainly sufficiently striking, and would appear to have other basis than the inevitable fallacy of statistics.

We have looked up the cases in the Out-Patient

Neurological Department of the Massachusetts General Hospital for the seven years 1896 to 1902 inclusive. This clinic draws its patients from widely diversified classes in the community, and from a large area outside of as well as including Boston. Out of 9,783 cases of nervous disease of various sorts, functional and organic, only five undoubted cases of multiple sclerosis were diagnosticated, with four probable cases. This is a vastly smaller proportion than from any of the New York clinics quoted above. Diffuse degeneration (Putnam-Dana type of combined sclerosis) and ataxic paraplegia were diagnosticated 28 times, and spastic paraplegia without further definition seven times. That some of these latter cases, at least, were multiple sclerosis rather than an isolated degeneration of the pyramidal tracts is highly probable, but not to be proved.

It should be said that the diagnosis of multiple sclerosis has not been made in the absence of tremor of the intention type, associated with speech disturbance or nystagmus or altered deep reflexes. The diagnosis has never been made in the presence of otherwise unexplained spastic conditions, or apparent hysterical states, unless tremor of characteristic type were an accompanying sign. Many of the patients coming to the out-patient department are naturally in early stages of disease, when the diagnosis, particularly in this affection, is often very difficult, if not impossible, to make with any degree of certainty. In contrast with these figures for the Massachusetts Hospital, one to about 2,000, are those for the Long Island Hospital for chronic disease, in which there were three cases among 255 of all sorts observed in the wards. Two other cases, not diagnosticated as multiple sclerosis during life, have shown the typical lesions of that disease post-mortem. However these figures may collectively be used, it is still perfectly apparent that the diagnosis of multiple sclerosis is made with very much less frequency in the Boston clinics under consideration than in New York and Edinburgh.

These statistics, in general, appear to show that Dr. Bramwell is right in his contention that multiple sclerosis is more frequent in Edinburgh than in New York or Boston; they certainly show that the diagnosis is more often made in those cities. It would, however, hardly be asserted that the conditions in New York and Boston are sufficiently diverse to account for the wide discrepancy in the number of cases diagnosticated in the two cities. It is also evident, for obvious reasons, that the number of cases diagnosticated in hospitals for chronic disease is relatively very much greater than in out-patient departments, as shown by Bramwell's, Onuf's, Fraenkel's and our own statistics from the Long Island Hospital.

The sources of error in such estimations, on the whole, seem too great to make such statistics of value, and for the following reasons: Multiple sclerosis is a disease extremely difficult of diagnosis in its early stages, and often in its late stages; clinicians differ widely in their interpretation of obscure signs and symptoms which may occur in, but do not characterize, multiple sclerosis; examination of out-patients is often of necessity too hurried and superficial to permit of accurate diagnosis.

In a recent excellent résumé of our knowledge of

¹ Jour. Nerv. and Ment. Dis., xxix, p. 238, 1902.

² Rev. of Neurol. and Psych., 1, No. 1, p. 12, 1903.

multiple sclerosis, Hoffmann³ speaks of it as one of the commonest of organic nervous diseases, and quotes Charcot's dictum: "*C'est une affection polymorphe par excellence.*" He alludes to upwards of one hundred cases, with three autopsies, observed by him at the Heidelberg Clinic, dwells upon the difficulty of diagnosis, and mentions twenty-three conditions which must be differentiated.

The possibility of distortion of statistics under these conditions of uncertainty, and the influence of the personal equation, is too great to make results of more than superficial value.

Medical Progress.

RECENT PROGRESS IN NEUROLOGY.

BY PHILIP COOMBS KNAPP, A.M., M.D., BOSTON.

EQUILIBRIUM.

By volitional equilibrium Babinski¹ means that form of equilibrium whose realization necessitates an act of the will, and which can be broken by the will. We cannot stand or extend the arm without volition, or change the position without a similar volition. Other forms of equilibrium may be due to the action of certain bodily functions, such as muscular tonus, and are involuntary. Equilibrium when the body is at rest is called static; when the body is in motion, kinetic. Normally kinetic equilibrium is more easily maintained than static; it is easier to walk than to stand without swaying, or to hop than to stand on one foot. In tabes static equilibrium may be affected before kinetic. This is shown most markedly when the patient is placed upon his back, with the thighs somewhat flexed on the pelvis, the legs on the thighs and the feet apart. In this position a patient with tabes, in whom the tactile sensibility, the sense of position and the sense of movement were well preserved, could not keep his legs still, although he was conscious that they were moving. Another patient with cerebellar disease, who was so ataxic that he could not walk without support, could, after some effort, maintain himself in a standing position for some time, his static equilibrium being so much better preserved than his kinetic equilibrium. When placed in the position above described, the legs were held even stiller than in a normal subject. Babinski concludes that in tabetic ataxia both forms of equilibrium are disturbed, but static equilibrium is at first the more affected. In cerebellar asynergy static equilibrium may be preserved after kinetic equilibrium is profoundly altered, and the power to preserve static equilibrium may sometimes be increased above the normal so much as possibly to amount to catalepsy, which may be due to a disturbance of the cerebellar functions. [Although the distinction between static and kinetic equilibrium is important, the test brought forward by Babinski is not decisive. Tabetic patients who have a decidedly ataxic gait, and are unable to stand with the eyes closed, can often keep their legs perfectly quiet. — REP.]

TOPOGRAPHICAL MEMORY.

Touché² defines topographical memory as the faculty of recalling the position of objects in relation to other objects which form their environment. This special memory is probably a part of the visual memory in general, but it may be lost when the special memories for form and color are retained. From two cases with autopsies, in which the topographical memory alone was affected, Touché concludes that this memory may be destroyed by a lesion of the inferior face of the left occipito-temporal lobe, especially of the fusiform convolution, but that even if the whole left visual field (cuneus, lingual and fusiform convolutions) be destroyed the memory for form and color may persist. The topographical memory, when active, enables the individual to direct himself where he wishes to go. Marie and Ferrand have maintained that this power might be lost even when a part of the visual field was left, and that the loss was related to a lesion of the inferior face of the left occipito-temporal lobe. Touché has studied four cases in which the faculty of directing one's self was lost, and three cases of lesion of the visual zone where this faculty was retained. Where the faculty was preserved, the lesions affected the cuneus and the lingual convolution, but the fusiform convolution was only very slightly affected. In the other cases the fusiform convolution was more or less involved. He therefore thinks that the topographical memory and the faculty of directing one's self may be located in the left fusiform convolution. In this connection a case carefully studied by Colucci³ is of interest. This was the case of an introspective student who, from childhood, had always had difficulty in establishing the topographical relations of objects, which became greater with increased topographical experience. The vision was apparently normal, the young man could distinguish details clearly and the disposition of individual objects; he could judge correctly the direction of a road or a distant building, and had no trouble if the objects were in a direct line; but if it were necessary to make any turning in his route, especially at the bifurcation of two ways, the whole horizon seemed to shift its position at the moment of deviation, so that a given road would seem to be almost at right angles to its true course. This was true of familiar streets, which he had traversed many times. He could, however, conceive and indicate localities, and it seemed absurd to him that the cardinal points could be displaced, yet actual experience produced this curious confusion. This illusion was of short duration, and on ultimate analysis usually consisted in changing the horizon so that the oblique line, considered in relation to the patient's frontal plane, was changed to a direct line. The illusion seemed to be based on the difficulty of conceiving any lines in space oblique to the frontal plane. Long residence in the country, where the topographical relations were less complex than in the city of Naples, and re-education by the aid of a compass, relieved the condition a trifle.

TABES DORSALIS.

Pathogeny.—Marie and Guillain,⁴ at a meeting of

³ Deutsch. Zeitsch. f. Nervenheilk., xxi, p. 1, 1902.

¹ Revue Neurologique, 30 May, 1902.

² Presse Médicale, 30 Nov., 1901.

⁴ Rev. Neurol., 31 Jan., 1903.

the Société de Neurologie of Paris, attack the hypothesis that the primary lesion of tabes is exclusively a root lesion. Without doubt there are lesions of the roots followed by true Wallerian degeneration in the posterior columns, but there are, in the posterior columns, other lesions not systematized in the course of any root fibers. In early cases, treated by the Marchi method, the changes in the posterior columns are diffuse, throughout the whole extent of the columns. In addition, the intramedullary lymph spaces are dilated, and when the central canal is permeable, blackish granules are found in the ependymal cells. When the process is very intense it may pass the limits of the posterior lymphatic system and extend into the lateral columns near the posterior horns, as in some forms of combined sclerosis, clinically closely resembling tabes. The predominant lesions of tabes are the non-systemic alteration of nerve fibers in the posterior columns, and a posterior meningitis most marked in the dorsal region. The pia mater has a lymphatic system, which in the posterior meninges has little or no communication with that of the antero-lateral meninges. The lymph spaces in the posterior meninges and posterior columns form a system particularly active and relatively independent, and Marie and Guillain believe that the tabetic process is simply a syphilitic lesion of this posterior lymphatic system of the cord. In the discussion that followed, Philippe maintained that in early cases he had found true Wallerian degeneration limited to certain root fibers. At a subsequent meeting Brissaud⁵ held that the existence of lesions elsewhere in the optic nerve, etc., indicated that tabes was a true degeneration of the centripetal protoneurones.

Juvenile tabes.—Maas⁶ reports six cases of tabes, all occurring before the age of twenty-five, and all in women. In these cases he found all the essential symptoms recognized in tabes of the adult, and is somewhat skeptical as to the existence of any peculiarities in the symptomatology of juvenile tabes. In three of his cases there were reasons for suspecting hereditary syphilis, but in the other cases no evidence of syphilis was obtained. The diagnosis of juvenile tabes has thus far rarely, if ever, been confirmed by autopsy, so that it is still doubtful how many of the cases are really tabes and not cerebrospinal syphilis. Apparently in juvenile tabes as in juvenile general paralysis, the reported cases show as many females as males, instead of the great preponderance of males observed in adults.

Senile tabes—At the congress at Toulouse, Pitres⁷ presented a study of senile tabes. Out of 350 cases observed by him 87, or 25%, were over fifty. In 55 of these cases, however, the disease began before fifty; in 32, tabes developed in persons already past fifty. These latter cases differ from those of ordinary tabes in certain particulars: they occur habitually in subjects whose arteries are markedly atheromatous, and syphilis is less frequently an antecedent. In tabes beginning after sixty-five years of age, syphilis was found in only 33%, while in tabes beginning before fifty it was found in 76%. The evolution of the disease is also more rapid in the senile cases, the motor symptoms appearing

early, and the pre-ataxic stage being correspondingly brief. Senile tabes, therefore, seems to be differentiated from ordinary tabes of middle life by its frequent occurrence in non-syphilitic atheromatous subjects and its comparatively rapid course.

Ankle reflex.—Goldflam⁸ thinks that the lancinating pains may often be the initial symptom of tabes, but there are cases in which the pains may be slight. He has personally never seen a case which had not pain or paresthesia in some form. The other symptoms of the triad—loss of knee-jerk and Argyll-Robertson pupil—are of course not detected until the pains or other symptoms demand medical aid. He reports a case in which the patient had had for ten years pains of the typical tabetic character. The most careful examination revealed no other symptom—the reflexes, the pupils, the sensibility, etc., were absolutely normal. Six years later Goldflam found unequal pupils, reacting to accommodation but not to light, and absence of the left ankle reflex. A few months later the right ankle reflex also disappeared. A year later, however, the right ankle reflex could be again elicited. The knee-jerks then were lively. Goldflam regards the ankle reflex as an extremely constant reflex, which is governed by the same laws as the knee-jerk. He holds with Babinski that it is regularly absent in tabes, often disappearing before the knee-jerk. In 116 cases of tabes he found the knee-jerk altered in 107. In 97 of these cases the ankle reflex was lost on both sides, in six it was lost on one side, in two it was unequal, and in two weak. In nine cases where the knee-jerk was normal, the ankle reflex was absent on both sides in five, on one side in three and unequal in one.

Optic atrophy.—Schupfer⁹ has studied the prognostic value of optic atrophy in 24 cases of tabes, 32% of 75 cases observed. He recalls the various opinions on the subject: that optic atrophy had a beneficial effect on the progress of the disease, especially the pains and ataxia; that it had a beneficial effect only when it appeared in the pre-ataxic stage; or that it had no effect at all. Schupfer concludes from a study of his cases, that when the disease begins with atrophy which goes on rapidly to amaurosis the pains are mitigated and ataxia is absent or slight in degree. When the atrophy appears during the course of the disease, the pains are generally mitigated, but the ataxic disturbances, if they have appeared, do not diminish. When atrophy causes speedy amaurosis the course is more chronic, and trophic disturbances are rare. The pains may disappear of themselves or be affected by treatment. Schupfer believes that the influence of blindness upon the ataxia is to be explained by the greater acuteness of other forms of sensibility in the blind, leading in the tabetic to a process of re-education of movements and an increased acuteness of the sensations governing them, such as is produced therapeutically by Frenkel's method of treatment.

MULTIPLE SCLEROSIS.

Bramwell¹⁰ calls attention to the greater frequency of multiple sclerosis in Scotland and the north of England than in the United States. In 2760 hospi-

⁵ Rev. Neurol., 28 Feb., 1903.

¹⁰ Rev. of Neurol. and Psych., January, 1903.

l patients he found 51 cases of multiple sclerosis, and in 3,065 private patients 49, or 1 in 58 of the total cases. This, furthermore, he thinks within the mark, as he has omitted doubtful cases which later might prove to be multiple sclerosis. He compares his figures with those published by the various New York neurologists in a discussion a year ago.¹¹ In 8,000 private patients there were 38 cases of multiple sclerosis, or 1 in 210; in 31,215 hospital cases there were 141 cases of multiple sclerosis, or 1 in 221. This gives a slightly exaggerated idea of the frequency of the disease in New York, as the same case may often have been reported by different observers; but Bramwell's statistics show that the disease is at least three and a half times more frequent in Scotland and the north of England than in New York.

Mackintosh¹² has studied the modes of onset in cases of multiple sclerosis observed in Ferrier's clinic, including only the cases exhibiting the well-known cardinal symptoms. In these 80 cases, tremor of the arms was present in 67, ataxia or slow movement of the arms in 5, nystagmus in 65, optic atrophy in 38, and scanning speech in 16. The earliest symptoms noted were motor paresis in 14 cases, sensory symptoms in 29 cases, ataxia or tremor in 20 cases, sphincter troubles in 5 cases, apoplecticiform attack in 3 cases, cerebral symptoms other than hemiparesis or apoplecticiform attack, including amblyopia, vertigo, diplopia, squint, nystagmus and headache, in 19 cases. Ten cases had acute or sudden onset. Purely unilateral symptoms were observed at the onset in 15 cases. The comparative frequency of sensory symptoms is also of importance, as contradicting the old teaching that sensory symptoms are absent, and as possibly facilitating the diagnosis of multiple sclerosis in cases which start under the guise of some other disease, such as spastic paraplegia.

Schupfer¹³ reports a case of multiple sclerosis with autopsy in a child of eleven, the symptoms beginning at the age of nine. He has also analyzed reported cases with two autopsies. The disease in childhood is often confounded with spastic cereoparalysis, Friedreich's ataxia, cerebellar ataxia, chorea, spastic paralysis, hysteria and pseudotuberculosis. The symptoms sometimes begin in childhood, but the disease may not assume a typical form until adult life. The etiology is uncertain. The symptoms may begin acutely in early childhood, and may follow some acute infection. The symptoms are very variable; motor disturbances are most pronounced in the legs, and disturbances of sensibility are very well marked; vesical disturbances are constant, and bed-sores often develop in acute cases. Oculo-motor and pupillary disturbances are quite common; but intention tremor, scanning speech and nystagmus are less common, and are apt to be transitory. Tremor of the legs is not uncommon. Mental symptoms are rare. Apoplecticiform attacks and convulsions are not often met with, but temporary disturbances of motion and sensation, of sudden onset and lasting a few days, are of importance. The course may be progressive, but the symptoms may slowly improve, and death is apt to be due to some intercurrent disease.

THE NEW YORK ACADEMY OF MEDICINE.

STATED meeting, March 19, 1903, under the auspices of the Pediatric Section. The President, ANDREW H. SMITH, M.D., in the chair.

SYMPOSIUM ON TYPHOID FEVER IN INFANTS AND CHILDREN.

DR. J. LOVETT MORSE of Boston read a paper on

THE OCCURRENCE OF FETAL AND INFANTILE TYPHOID.

In consequence of the inherent difficulty in making the diagnosis, he said, little reliance was to be placed on the earlier data; but since the discovery of the typhoid bacillus and the employment of the Widal test, evidence of some real value was available. He spoke first of the abortion type, and stated that abortion in women suffering from typhoid was principally due to high temperature and the death of the fetus. The latter was generally regarded as the most common cause. In fetal and congenital typhoid the child is either born dead or dies soon after birth. It was necessary to exclude all cases reported before the time of diagnosis by the typhoid bacillus and also doubtful cases since then. There were now fifteen cases proved by bacteriological examination in autopsies and one by the serum test. In children with typhoid, who were born dead or died soon after birth, it was believed that the infection was conveyed from the mother to the fetus through the placenta. He mentioned a case in which twins were born alive at the eighth month, both of which showed the Widal reaction. On the fourth day the temperature of both was 104°, and one died on the fifth day and one on the sixth. In Bell's case the Widal reaction was seen four weeks after birth, while absent in the mother.

If these children are born alive they generally die at an early period from cachexia. From the results of autopsies it is concluded that lesions characteristic of typhoid do not occur until some time after birth. It would seem, therefore, that the infection is not perfected in fetal life, being general in character and without especial local manifestations. The typhoid bacillus is found in the spleen in most cases. The septicemic nature of the infection accounts for the extreme mortality in fetal and congenital typhoid. The infection may be conveyed from the mother through both the normal and abnormal placenta. The non-use of the intestines during fetal life, as well as the general character of the infection, would account for the absence which has been noted of any implication of the bowel; but in infants who have lived three weeks, intestinal lesions may be found. While death is the usual result, recovery may take place. It is possible that the fetus may pass through the infection and be born alive and well, but no proof of this exists.

In regard to infantile typhoid, there is much difference of opinion as to the frequency of the disease in the first two years of life. There is no very evident reason why the infant should be exempt from the infection; in fact, it would seem reasonable to suppose that this class of subjects should be more liable to contract it than older ones. In the first

year, it is true, the breast-fed child would naturally be practically exempt, and the heat employed in the preparation of the food of the artificially fed would diminish the chances of its contraction. In the second year, however, the large amount of cold milk consumed would seem to render the child particularly subject to the risk of typhoid. Nevertheless, the statistics at command are very uncertain. There is an *apparent* infrequency of the disease during the first two years of life. Whether this rarity is an actual fact or whether typhoid occurs frequently in infants without being recognized, it is as yet impossible to say. Its relative frequency can be determined only by a more general use of the Widal reaction in the illnesses of children, particularly those of a diarrheal nature, and of routine bacteriological examinations. A large series of cases is necessary.

In ten infants who recovered, the average duration of the disease was twenty-one days, and in ten who died, eighteen days. The course is shorter than in adults, and it is possible that many mild cases may escape detection. The Widal reaction and culture of the typhoid bacillus present the same results as in adults. In the light of our present knowledge it may also be said that the symptomatology is the same as in them.

DR. J. P. C. GRIFFITH of Philadelphia read a paper on

THE OCCURRENCE OF TYPHOID IN INFANTS AND CHILDREN.

He said that he had very little to add to what he had already said in previous papers, but he would endeavor to point out some of the peculiarities of the disease as it occurred in this class of subjects. As to the etiology, this was, of course, the same as in after life, and it could be shown that many children were sufferers from typhoid during the milk epidemics which occurred from time to time. He gave the statistics of typhoid in fetal life, so far as these could be considered reliable, and said that in these cases the infection was evidently conveyed through the placental circulation. It was his own belief that typhoid was far less rare in infants than was generally supposed. It was not a very rare affection, though less frequent than in adults. He would not say that it was common; *comparatively rare* was perhaps the best term to use in regard to it. Having given such statistics as seemed available, he went on to say that breast-fed infants were naturally exempt. In infants of two years and under the disease differs principally from that met with in older persons, (1) in its onset and shorter course, and (2) in that the nervous symptoms overbalance the intestinal. Walking cases are far more common than in adults. On the other hand, in exceptional instances, the onset may be remarkably sudden. The intestinal symptoms are usually very mild. Ulceration of the bowels is rare, and generally the only lesion found in them is more or less diffuse inflammation. Vomiting occurs in a considerable number of instances. Epistaxis is not so frequent as in adults. Some degree of cough, with mucous râles in the chest, is very commonly met with. Diarrhea is not infrequent in the first two and a half years of life. Out of 417 cases, it was noted in 113. Its fre-

quency in infants appears to be due to the general tendency to diseases of the intestines in them.

In early childhood diarrhea is less frequent, and does not often give trouble. During the past season there has been but little diarrhea among the cases in the Children's Hospital in Philadelphia. In the wards of this institution there is constantly more typhoid fever than any other disease, the patients ranging in age from three months to twelve years; and Dr. Griffith said that at the clinics where the students became surfeited with this subject from the many cases shown there was often a scarcity of other material to present. Abdominal pain is not infrequent, but tympanites is not a prominent feature. Rose spots probably appear in the majority of cases. Nervous symptoms unquestionably preponderate over the intestinal ones. At the same time, these may not be very marked. The low, muttering delirium, subsultus tendinum, etc., so commonly met with in adults, are very rare except in patients approaching the age of puberty. Still, there is often a slight degree of apathy and slight delirium, as well as more or less headache. In a few cases a pseudomeningitis is observed. He referred to one in which the attack was ushered in with wild delirium. All the signs pointed to meningitis, but the Widal reaction was obtained, and after a comparatively short time the excitement entirely subsided.

The average duration of the disease is from fourteen to twenty-one days. The temperature is somewhat variable. The spleen is always enlarged, and the mesenteric glands are commonly much swollen. The solitary and agminated glands are inflamed and show some tendency to ulceration, and the older the child, the more likely this is to occur. In the fetus no evidences of intestinal ulceration are found. In making a diagnosis between typhoid and diarrheal affections, such as enterocolitis, as well as meningitis, the Widal reaction must often be depended upon. Influenza offers peculiar difficulties in the way of diagnosis. Whenever there is abnormal temperature which continues for some time without apparent cause, typhoid should be suspected. It is to be noted that the Widal reaction may be very late in making its appearance. Aphasia is said to be more frequent than in adults. He had met with *nomâ* in several instances. Intestinal hemorrhage is rare. Perforation is very rare, and when it occurs it is for the most part in children approaching puberty.

The prognosis is, on the whole, good in children. This is not the case, however, in infants. Dr. Griffith's figures show a mortality of 27.07% for all cases under two and a half years. In infancy it is, therefore, a distinctly dangerous disease.

As to the treatment, it is a question to what extent hydrotherapy is of value. The typical Brand method, it may be said, is seldom applicable. Children as a rule do not tolerate it well. It is very apt to give rise to a weakness of the pulse, which continues for an hour or an hour and a half after the bath. In many cases general sponging also seems to do harm, and a brief immersion is usually preferable to this. Sponging the feet is often sufficient; if not, it may be followed by a carefully graduated bath. The abdominal ice bag generally works well. We can afford in many instances to let the temperature alone, and there is reason to believe that hydrotherapy often does more harm than good.

DR. A. D. BLACKADER of Montreal, Can., read a paper on

THE SYMPTOMS AND ETIOLOGY OF TYPHOID FEVER IN CHILDREN, MAKING SPECIAL REFERENCE TO THE WIDAL REACTION.

In speaking of the etiology, after referring to the ordinary agency of milk, water, etc., he mentioned the conveyance of infection by means of the child's fingers, by flies and by wind-driven sand. In the city of Tunis, where all the refuse is thrown in the streets, he had been informed that 75% of the cases of typhoid occurred in children. In early childhood there is less susceptibility to the disease than later. In children, as a rule, typhoid runs a milder and milder course than in adults. They appear to offer a greater resistance to the infection, and to overcome it more readily. As to differences in susceptibility, children who show a tendency to steric disturbance seem to be much less liable to have typhoid than those subject to intestinal trouble, and it may be that the acid secretions of the stomach have something to do with this comparative immunity. On the other hand, hyperemia or other abnormal conditions of the intestines would appear to constitute a predisposing factor as regards this disease. Another predisposing factor is the lowering effect of other diseases. There may, in fact, be a double infection, as the scarlatinal and typhoid; the typhoid bacillus has been found in the blood of patients suffering from scarlet fever. Intention at the same time has also been observed with meningitis.

In children with typhoid the fever shows greater instability and is of shorter duration. The onset of the attack is apt to be more sudden than in adults, and may simulate pneumonia. In a considerable number of instances it is very insidious. Not infrequently the temperature is much the same as that which characterizes the disease in adults. The pyrexia may reach a high point, and in some cases is of a remittent type. True intermittent is seldom seen in the typhoid of children. In the larger proportion of cases the fever has run its course by the end of the third week. It is found, however, that during convalescence there often occur elevations of temperature which may be due to a variety of causes. Thus, any excitement or unusual exertion may bring it on. Abortive cases are not infrequent, in which the pyrexia terminates after the eighth or ninth day. There is also the possibility of a typhoid infection running its course without any pyrexia, and he met with no cases of this kind, in 1901. The mortality of the disease is small in children. Out of 101 cases reported by him in 1900 there was but one death. When a fatal result does occur, it is usually from some intercurrent affection.

The spleen is undoubtedly always enlarged, though its increased bulk cannot always be detected. Gurgling in the ileocecal region is a sign of little value, but tenderness here is worth noting. It calls for a careful differential diagnosis from appendicitis. Rose spots occur in the great majority of cases, and exceptionally they appear as early as the fourth or fifth day. Desquamation is not generally noticed. Some amount of bronchitis is seldom wanting, though there may be only a very

moderate cough present. This is one of the ordinary expressions of typhoid in children. The circulation does not appear to suffer to the same extent as in adults, and only in very severe cases is cardiac asthenia observed. A transient intermittency of the pulse, however, is not uncommon. Diroticism is almost never met with under the age of ten years. More or less tympanites is usually present. The nervous symptoms are not marked, though there may be some headache and apathy. Pseudo-meningitis occasionally obscures the diagnosis, but the rounded abdomen, the enlarged spleen and the rose spots should enable us to decide the true nature of the case. Nephritis is an occasional complication in older children. Eberth's bacillus may develop in the urine and set up a cystitis. Recrudescence of fever may occur in consequence of complications, such as otitis, fecal impaction, etc. It must be distinguished from true relapse, which is decidedly less frequent than in adults.

In making tests for typhoid Dr. Blackader has been accustomed to use Ehrlich's, as well as Widal's, method. Widal's reaction, he thought, should be sought for every second day. In a series of fifty cases it was found by the tenth day in nineteen; between the tenth and twentieth day, in twenty-three; and between the twentieth and thirtieth day, in four; in one case the reaction was not obtained until the forty-sixth day, and three cases failed to give any reaction. No note had been made of the time of the disappearance of the reaction.

DR. L. EMMETT HOLT said that in his experience, as well as that of others, typhoid was exceedingly rare in infancy in New York. It was infrequently met with in older children also, and he had been much struck with Dr. Griffith's account of the large number of cases treated at the Children's Hospital in Philadelphia. At the Babies' Hospital in New York there had been but three cases in the last fourteen years, and they had all occurred in patients over two years old. Even if the Widal reaction were sought for in every case in which there was any possibility of the existence of typhoid, he believed that the actual number of cases of the disease would be found to be very small. It was true that cases were sometimes met with which, for want of a better name, Dr. Delafield had designated as "New York fever," for which, after excluding other diseases, and especially malaria by the use of quinine, there did not appear to be any assignable cause. Yet he did not think there was any reason whatever to consider these cases as typhoid. In this city, at least, the presumption in any doubtful case of fever in a patient under two years of age was *against* typhoid. In regard to peculiar phases in the typhoid of children, he had found it much more frequently a cerebral than an intestinal disease. As to the eruption, he had seen two or three cases in which it was so profuse that the disease was mistaken for measles. It had been his fortune to meet with quite a number of instances of this very abundant rash. He believed that attacks of acute indigestion were very apt to precipitate the development of typhoid when the bacilli of that disease were present in the intestinal canal.

DR. W. P. NORTHRUP made some remarks, which were principally devoted to a criticism of Dr. Grif-

fith's position as to the frequency of typhoid in infants. He explained that there was an "old feud" between them on this subject. He took issue with him particularly for excluding from his statistics the figures of the New York Foundling Hospital and the New York Infant Asylum, two of the largest institutions of the kind in the country, in which were given the observations of such men as the late J. Lewis Smith and James O'Dwyer, as well as of Dr. Holt and himself. He said that he had once heard of a man who had been called by the nickname "Statistics," because he was such a notorious liar. In his last published paper Dr. Griffith had given 417 cases as the total number that had been known to occur in infants under the age of two and a half years in all the earth. Of this number 91 were not altogether free from doubt; so that the actual number of undisputed cases was only 326. Dr. Northrup then gave the number of cases of typhoid fever in the United States in a single year, according to the twelfth census, and went on to say that when the 326 was compared with the untold millions of cases of typhoid which had occurred in the world, it could hardly be said that typhoid in infancy was a very frequent disease. The records of the New York Foundling Hospital showed that there had not been a single case there in twenty-five years. Further academic discussion of this matter he thought was absolutely useless. Nothing but the Widal test could determine the question.

Recent Literature.

Manual of Antenatal Pathology and Hygiene. The Fetus. By J. W. BALLANTYNE, M.D., F.R.C.P.E., F.R.S. (Edin.), Lecturer on Midwifery and Gynecology, Medical College for Women, Edinburgh; Lecturer on Antenatal Pathology and Teratology in the University of Edinburgh (1900); Examiner in Midwifery in the University of Edinburgh; Assistant Physician, Royal Maternity Hospital, Edinburgh; Honorary Fellow of the Glasgow Obstetrical and Gynecological Society, and of the American Association of Obstetricians and Gynecologists. Pp. 527. New York: William Wood & Co. 1902.

The author of this book has already become widely and justly known by the large amount of original investigation performed by him, and by his numerous writings, chiefly on the subjects connected with fetal pathology. Among the more important of these is the two-volume edition on "The Diseases and Deformities of the Fetus," published in Edinburgh, while in this country his article published in Keating's *Cyclopedia of the diseases of children* on "Congenital Disorders and Diseases of the New-born" is noteworthy. He is also the originator of the idea of a prematernity hospital, which is fast coming into favor and is undoubtedly bound to have a place in connection with lying-in hospitals in the near future. Dr. Ballantyne has not been the only investigator in the field of research of fetal pathology, but he has had the unusual fortune to have had nearly three hundred specimens for examination, comprising nearly all the morbid fetal types. He is thus emi-

nently qualified to speak with authority and from a scientific standpoint.

This volume of *Antenatal Pathology and Hygiene* is to be followed by a companion volume on *Teratology and Morbid Heredity*. The book is divided into two parts, Book I, "Antenatal in Relation to Postnatal and Neonatal Pathology," and Book II, "The Pathology and Hygiene of the Fetus."

In Book I is given an interesting account of the history, literature and growth of fetal pathology, and in it the statement is made that fetal pathology is one of the last provinces of medicine to have emerged from a kind of medieval wonderland into the realm of science. Considerable evidence, however, might be brought forward to prove, as shown in some recent medical publications, that the emergence is not even now altogether complete. The author points out the relationship of surgery and gynecology to antenatal pathology, and emphasizes the fact that many of the conditions in life embraced by the former are due to intrauterine factors. He also notes that in the last decade great improvements in obstetric and operative technique have been made, but that in the pathology of pregnancy the same degree of progress has not been made as in other spheres of medicine. The last two chapters in Part I, the most valuable from a practical standpoint, are devoted to the more common pathological conditions — accidents and infections occurring in the newborn.

The major portion of the work and by far the most important is devoted to Part II, which treats of the anatomy, physiology and diseases of the mature fetus. The author's classification of fetal diseases, or fetal morbid states, is interesting in showing the elaborate manner in which this portion of his subject is treated. It comprises, I, Transmitted Diseases; II, Transmitted Toxicological States; III, Idiopathic Diseases; IV, Neoplasms; V, Traumatic Morbid States; VI, Diseases and Morbid Conditions of the Fetal Annexa; VII, Pathology of Fetal Death. A chapter is also devoted to various ill-defined morbid states of the fetus, occurring in connection with certain diseases in the mother, as eclampsia, cancer, etc. The work in no way treats of embryological conditions, and in this connection the author's definition is interesting that, "fetal pathology is characterized by disease as distinguished from embryonic pathology, which has malformations and monstrosities as its peculiar possession."

The discussion of the subject of placental transmission is excellent, and should be read by every one who is at all interested in the matter. The author does not allow that the fetus is protected by the structure of the placenta from the bacteriological diseases, or that it is necessary to admit the existence of a placental lesion to explain the passage of microorganisms. He states that fetal death is confessedly a failure and a disappointment, and treatment unsatisfactory, but he ventures the opinion that as the means for rearing premature infants are perfected, even the certain cause of fetal death, expulsion before the sixth month, may become less sure and the date of viability may thus be pushed further back. In this connection it is tersely stated that, "when the birth-rate begins to go down, the value, economic as well as sentimental of the unborn infant, begins to go up." In his conclusion the author says it is beginning to be evident that inherited diseases and

anomalies are rather signs of the breaking of heredity than instances of the persistence of it; that the tendencies of the germ plasma are towards the formation of normal structures, and that much of the harm that is done to the germ in one generation may be undone in the next, if it be permitted.

Much of value might be quoted from this most interesting and instructive book, and it has been a pleasure to read it for review. No equally satisfactory book on the subject has ever been produced, and it is a cause for congratulation that the writer is English and that the book is published in the English language. It should be widely read, and is particularly commended to those especially interested in children's diseases and in obstetrics.

The American Text-Book of Obstetrics. In two volumes. Edited by RICHARD C. NORRIS, M.D.; Art Editor, ROBERT L. DICKENSON, M.D. Second edition, thoroughly revised and enlarged. Two imperial octavo volumes of about 600 pages each, nearly 900 text illustrations, and 49 colored and half-tone plates. Philadelphia; London: W. B. Saunders & Co. 1902.

The second edition of the "American Text-Book of Obstetrics" has outgrown the single-volume size, and while there is little doubt but that in the present condition it would be rather cumbersome for one volume, it is a question if the editors would not have done better to have eliminated certain portions in order to bring this edition within the limits of a single volume. A book of one volume is easier to consult for reference, and as a textbook is unquestionably much superior for the use of the medical student.

The volumes themselves are most attractive, and are profusely and splendidly illustrated, some of the illustrations being new in this edition, while very few of them have ever appeared in other textbooks. It certainly is refreshing not to have to see again the old time-worn illustrations which have been reproduced so often, and often without reason.

The introduction of an art editor is a feature of this book, and in general the art editor has performed his work very well, and the great majority of the illustrations show as well as they may what it is intended they should. The art side might, however, be considered over-developed in certain instances, as when the nude figure of a woman, with the "pose from Spigelius," is used to indicate the location and intensity of the fetal heart sounds, the abdominal flaps being turned back and delicately held in the fingers of the woman herself; or again when a reclining figure "after the Ariadne" is taken to show the relative location of the iliac spines and the lumbar vertebrae.

The list of contributors has been changed only slightly, as necessitated by the deaths of Drs. Parvin, Etheridge and Earle, and by the addition of Dr. J. Clarence Webster. The work remains a collection of most excellent obstetrical monographs; probably a better one could not be obtained elsewhere, all things considered. There appear, however, some statements which should be eliminated from a modern book of this character at the beginning of the twentieth century. That monstrosities result from psychical influences or from maternal impressions is not supported by scientific opinion at

the present time. Moreover, one would scarcely expect to find such directions as to cover the vulva, as the head begins to emerge, with sterile lint, in order to prevent the entrance of microbes from the air in the room. Or that in many respects country practice exposes the patient even more to infection than does city life, because manure is spread over the fields and the garden close to the house in which live the farmer and his wife; and also because the butcher kills his cattle, lets the blood soak into the ground, and nails the skins to the barn-doors, whence their odor can be smelled far away. In another place the same writer says that an epidemic of puerperal fever in a new maternity hospital on Blackwell's Island was probably due to the manure with which the surrounding grounds had been covered in order to make a garden.

The work is comparatively free from contradictions, but such will creep into any book written by different men on the system plan, no matter how carefully it may be edited. As an illustration in one chapter it is stated that during the fortnight preceding parturition a genuine broadening of the cervix takes place, when the cervical canal is merged into the upper uterine cavity; while in another chapter the writer has given precedence to the views of those investigators who believe that the cervix remains unchanged until the beginning of labor. In one chapter the writer carefully describes the modern nomenclature of the abbreviations now in general use for designating the various positions, as O. L. A. and O. D. A.; while, in another chapter, presumably another writer reverts to the old method of designation by L. O. A. and R. O. A.

The details for the conduct of an aseptic labor, than which there is nothing more important in the management of normal labor, are given at considerable length with an alternative of several methods. We believe it would be better, however, to give one method, the best and the simplest, than to offer a choice of several; and to advise the use of one antiseptic only, that one which time and experience have proved to be the best and most reliable under all conditions. Advice for use of rubber gloves is given only after septic contact. The dangers of frequent internal examinations are well emphasized, while the details of the external examination for obstetric diagnosis are thoroughly described and very fully illustrated.

There is throughout the work a certain tendency towards verbosity, and consequently a considerable portion of the text might be eliminated with profit and thereby make a better textbook and less of a treatise.

Taschenbuch der Massage für Studierende und Ärzte. Von DR. ERICH EKGREN, an der III medicinischen universitäts-klinik zu Berlin. Mit einem Vorwort von Geh. Med.-Rath. Prof. Dr. H. SENATOR. Berlin: Verlag von S. Karger. 1903.

This is a small book of ninety pages, on the general subject of practical massage, written by a man of experience. The treatment of the subject is scientific. It is well condensed and sufficiently illustrated to make clear the important procedures. The book may certainly be recommended as a brief compendium on an important subject.

THE BOSTON
Medical and Surgical Journal

THURSDAY, APRIL 9, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (INCORPORATED),
283 WASHINGTON STREET, BOSTON, MASS.

THE SALE OF POISONS.

A REPORT¹ has recently been made to Parliament by a committee appointed to consider the question of revising the list of poisons which in England can be sold only under definite restrictions. Under the Pharmacy Act of 1868, and its subsequent amendments, two lists of poisons were prepared. The first list consists of certain violent and dangerous poisons, which can only be sold under regulations, which require that the buyer should be known to the seller, or should be introduced by some one who knew both parties. Registry of the sale should also be made, in a book kept for the purpose, of the date of sale, name and address of the purchaser, name and quantity of the article sold, and the purpose for which it is stated to be required. The second list consists of articles to which it is only necessary to attach a label, giving the name of the article, the word "Poison," and the name and address of the seller. This requirement also applies to all articles in the first list.

The committee held several sessions and listened to much valuable testimony. Among other facts it was shown that deaths had occurred from the following patent medicines containing poisonous substances: Battle's Vermin Killer; Chlorodyne; Winslow's Soothing Syrup; a patent medicine containing antimony; Martin's Pectoral Balsam; Hooper's Whooping Cough Mixture; Holt's Whooping Cough Specific; Indian Tincture; Bentley's Weed Destroyer; Rough on Rats; and Phosphorus Paste.

The following are the amended lists recommended by the committee:

PART I.

Arsenical and its preparations.

¹ Report of Committee to Consider Schedule A of the Pharmacy Act of 1868. London, 1903.

Alkaloids. All poisonous vegetable alkaloids and their salts.
Aconite and its preparations.
Atropine and its preparations.
Cantharides.
Cocaine and its salts.
Corrosive sublimate.
Cyanide of potassium and all metallic cyanides.
Emetic tartar.
Ergot of rye and its preparations.
Morphine and its salts, and preparations containing one or more per cent of morphine.
Picrotoxin.
Prussic acid and its preparations.
Savin and its oil.
Strychnine and its preparations.
Vermin killers containing any of the foregoing poisons.

PART II.

Acetanilide and its preparations.
Almonds, essential oil unless deprived of prussic acid.
Belladonna and its preparations.
Cantharides, tincture and vesicating liquids.
Carbolic acid and liquid preparations containing more than 3% of acid.
Chloral hydrate and its preparations.
Chloroform.
Cocaine, preparations of.
Corrosive sublimate, preparations of.
Digitalis and its preparations.
Morphine, preparations containing less than 1%.
Nux vomica and its preparations.
Opium and all preparations of opium and poppies.
Oxalic acid and its soluble salts.
Precipitate red.
Precipitate white.
Mercuric iodide.
Mercuric sulpho cyanide.
Strophanthus and its preparations.
Sulphonal.

In consequence of the increased use of poisons among farmers and gardeners for use as insecticides, sheep-dips, weed-destroyers, etc., the committee thought it best to recommend a third list of poisons to include such substances.

This list consists of preparations of arsenic, tobacco or carbolic acid, to be kept in closed vessels, distinctly labelled as "Poisons," with the name and address of the seller and the purpose for which the article is made or intended.

In Massachusetts laws were enacted of a similar character in 1887 and 1888, limiting the sale of poisons, and until 1896 this law was applicable to all poisons, except those sold for agricultural purposes. But in that year the active interference of the Patent Medicine Trust was sufficient to secure the enactment of an amendment providing for the exemption of "patent and proprietary medicines" from the action of this law.

An investigation by the State Board of Health had shown that certain patent medicines, for exam-

ple, many catarrh cures, contained cocaine in such quantities as to seriously injure the health of those who used these preparations, and caused them to unwittingly become the victims of a dangerous habit. Certain cosmetics were found to contain dangerous quantities of corrosive sublimate and lead, and instances of harm were known to be due to their use. The law had no intention of preventing the sale of these articles, but only required the application of poison labels to the packages, so that the user might be cautioned as to their use.

The State Board of Health entered complaint in court against parties for the sale of such articles, among them being two so-called "Mesdames," the proprietors of face or complexion bleaches, who were accustomed to proclaim their wares in public halls, accompanied by orchestral music. This action of the board had a salutary effect, but was short-lived, since the amendment secured by the patent medicine interest prevented further action in this direction.

During the present session of the Massachusetts Legislature the subject has again come up, in the form of an order, requesting the State Board of Health to report "whether, in the opinion of the board, there is anything dangerous to public health in the sale and use of articles commonly known as face bleaches, and if so, what, in the opinion of the board, is necessary in the way of legislation to protect the public against the sale of such substances."

In reply to this order the board collected such preparations of this character as could be found in open market, and had them submitted to analysis.

Some were found to contain dangerous poisons, others were quite free, and the board suggested that the law relating to the sale of poisonous proprietary medicines which was in force prior to 1896, requiring a poison label to be affixed to such articles, would, if re-enacted, provide a greater degree of protection than is possible under existing statutes (Senate, No. 310, 1903).

EXPERIMENTAL EVIDENCE OF THE EFFICIENCY OF FORMALIN INJECTIONS IN SEPTICEMIA.

SINCE the case of streptococcus septicemia recently reported by Dr. Barrows of New York, in which recovery followed the intravenous injection of formalin solution, naturally much interest has again been directed to this possible method of treating a formidable condition. A certain amount of experimental evidence, to which we have previously alluded editorially, was already available, and we are glad to make note of a further research, conducted under the auspices of Dr. William H. Park

of New York, on the effect of such injections in septicemic conditions. The experiments, which are published in the current number of the *Medical News*, were carried out on rabbits, with the general result that streptococci were shown to increase in the blood, even after large doses of formalin, and that death might still be caused by septicemia. More than this, it was apparently shown that all the rabbits receiving formalin after the streptococcus died earlier than those receiving the streptococcus alone. Further experiments conducted with a virulent culture of pneumococcus gave similar results. The formalin failed to give the slightest protection. Tables are appended which show that injections of formalin in some cases were given far beyond the comparable dose advised by Dr. Barrows for man, but without protective effect. In spite of the relative fewness of the experiments, the results were so wholly uniform as to lead the writers of the article, Drs. Park and Payne, to the conclusion that non-lethal formalin injections are incapable of checking a septicemia once started in healthy animals.

The whole matter is naturally one of very great practical importance, and fortunately one which may be in great measure experimentally verified. The work hitherto done in testing the efficiency of formalin injections has certainly not been sufficiently encouraging to justify their routine use in man. It is always possible, and in fact probable, that the conditions in human beings are somewhat different from those in the lower animals; nevertheless, such experimental evidence as we have, must be given very great weight and lead to conservatism in this somewhat radical method of treatment.

THE BOSTON FLOATING HOSPITAL.

THE work of the Boston Floating Hospital has increased year by year until now, as we have previously had occasion to state, it has quite outgrown the facilities with which it is at present provided. Naturally, the need of a new boat, with larger opportunities, both for the care of the patients and for their adequate study, is demanded. In spite of the fact that last summer was a particularly cool one, there was a waiting list of permanent patients during the greater part of the season, so that the hospital was maintained in operation until the middle of September. It should be recognized that this summer work for children has a broad field of operation. While it is true that most of the patients come from Boston and its immediate vicinity, some are brought from cities and towns at a distance, and other hospitals are availing themselves of the peculiar opportunities which the Floating Hospital offers for the care of children during the summer.

A further element in the work is the opportunity afforded for careful and systematic investigations into the diseases common to children during the heated term. It is stated that Dr. Simon Flexner is interested in determining the value of the serum which he has been elaborating for the treatment of the summer diarrhea of children. To this end it is designed to send competent men to test the value of the serum at various children's summer hospitals. It is evident that with a larger boat, and consequently improved laboratory facilities, much could be done here toward elucidating this and other problems which are constantly being presented.

MEDICAL NOTES.

PREVENTIVE AND CURATIVE PROPERTIES OF TYPHOID PLASMA.—Dr. Macfadyen has made a further communication to the Royal Society in regard to the preventive and curative properties of typhoid plasma. From experiments made upon monkeys and control experiments upon guinea pigs, he concludes that: (1) By the injection of the intracellular juices of the typhoid organism into the monkey it is possible to obtain a serum with both antibacterial and antitoxic properties. (2) Such a serum possesses curative and preventive properties as regards the typhoid bacillus and an intracellular toxin present in the same organism.

PORTRAITS OF DOCTORS.—According to the London letter of the *Medical Record*, cartoons, published in *Vanity Fair*, have reached the number of eight hundred, among which are thirty-six doctors. These portraits of doctors are now offered by the publishers for £2 2s. Single portraits may also be purchased at varying prices; for example, Sir S. Wilks is priced at 2s. 6d., Sir F. Treves at 1s., and Sir W. Broadbent at 6d.

ONE HUNDRED AND THIRTIETH ANNIVERSARY OF THE MEDICAL SOCIETY OF LONDON.—It is stated in the same letter that the Medical Society of London celebrated its one hundred and thirtieth anniversary on Saturday by a dinner, to which nearly two hundred persons sat down. Sir William Church proposed the toast of the society, to which Mr. Gould, the president, responded. The Hon. R. P. Porter, U. S. A., responded for the guests, as also did the Lord Chancellor.

CONFEDERATION OF MEMBERS OF RECIPROCATING STATE MEDICAL EXAMINING AND LICENSING BOARDS.—A meeting of this confederation is to be held Thursday, April 23, in Chicago, the object being to take further action whereby practical and effective reciprocity may be had in the near future between the different states of the Union. It is hoped that delegates from various states will be present.

A GIFT FOR THE PASTEUR INSTITUTE.—It is stated that Dr. Emile Roux has recently been awarded the Osiris prize amounting to \$20,000, and that he intends to transfer the amount to the Pasteur Institute, of which he is sub-director.

A CENTENARIAN PHYSICIAN.—It is reported that Dr. John H. Woods of Thomas, Okla., died March 28, at the age of one hundred and one years. He had been actively engaged in practice for seventy-five years.

AN ANTISMOKE ORDINANCE.—According to *American Medicine* an antismoke ordinance has been passed by the Chicago City Council. The ordinance requires the department for the inspection of steam boilers and steam plants to pass on smoke devices and plans for constructing steam plants, and also requires the supervising engineer to give the owner of a smoke-making plant such advice and assistance as will in his judgment prevent the emission of dense smoke.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, April 8, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 50, scarlatina 35, typhoid fever 10, measles 37, smallpox 0.

AN AWARD OF FULL DAMAGES.—In a damage case recently tried in Salem, it is reported that the plaintiff received the full damages asked for, for injuries alleged to have been received while riding on one of the defendant's cars. Such an award in full is unusual.

BEQUEST FOR A HOSPITAL.—It is reported that Mrs. Elizabeth R. Stevens has given a sum of money amounting to about \$100,000 toward the erection of a new hospital in Fall River, contingent upon the further collection of \$100,000.

NOISE AS AN ELEMENT OF DAMAGE.—The Supreme Court has confirmed the ruling of the chief justice of the Superior Court that noise is an element of damage. The question arose through the operation of the Boston Elevated Railway, leading to the institution of various suits along its line for damages due to noise. The full text of the decision is of very great interest in relation to this matter, which naturally affects directly a large number of persons and indirectly the entire community.

DECISION AGAINST ANTIVACCINATIONISTS.—In a test case regarding the constitutionality of compulsory vaccination the supreme bench of the full Court of Massachusetts has rendered a decision upholding the lower court in its ruling that compulsory vaccination is constitutional. The court, in rendering

this decision, recognized the possibility of injury from vaccination in individual cases, but held that a measure of such accepted value should not, therefore, be evaded. Attention was also drawn to the fact that the authorities have not the power to vaccinate by force, and that the worst that could happen to an individual objecting to the operation was the payment of a fine of \$5.00. This ruling is quite in accord with the best public opinion on this subject.

NEW YORK.

FREE BED IN MONTEFIORE HOME.—The Montefiore Home and Hospital for Chronic Invalids has been presented with \$2,500, for the endowment of a bed, raised by a league of young people organized in the interests of the institution.

MORTGAGE ON ST. MARK'S HOSPITAL PAID.—The executive committee of the managers of St. Mark's Hospital announces that a mortgage of \$5,000 on the hospital has been paid off by a subscription raised during the past three months.

REGULATION OF BARBERS.—The State Senate at Albany has passed a bill "regulating the practice of barbering, and to establish a State Board of Barber Examiners, and provide for sanitary inspection of barbers' shops."

MORTALITY IN MARCH.—The mortality in the city during the month of March represented an annual death-rate of 19.67, against 20.81 in February and 19.76 in March, 1902. This is a very gratifying showing for what is often the worst month of the year. The most noticeable decrease is in the deaths from diseases of the respiratory system, and this is no doubt largely due to the exceptionally mild weather which prevailed. The weekly average of deaths from pneumonia declined from 196.5 in February to 178.5 in March; of deaths from bronchopneumonia, from 90.75 to 83.25; from acute bronchitis, from 49 to 37.5, and from pulmonary tuberculosis, from 182.25 to 171. The weekly average of deaths from organic heart diseases decreased from 108.25 to 100.75. There was very little change in the number of deaths from the zymotic diseases, the weekly average from diphtheria continuing about 45; from scarlet fever, about 17; from measles, about 10; from whooping cough, about 8, and from typhoid fever, about 10. There were no deaths from smallpox. Among the diseases which showed an increased mortality were cancer, the weekly average of deaths from which rose from 53.75 to 55, and Bright's disease and nephritis, in which the average rose from 125 to 130.5. The weekly average of deaths from influenza was 33.25 in March, against 34.25 in February. While this is a decrease of only one death a week, the disease really seems to be on the wane,

for while 52 deaths were reported from it during the last week in February, there were only 27 deaths ascribed to it in the last week of March.

Correspondence.

LETTER FROM THE PHILIPPINES.

SPECIAL CORRESPONDENCE.

MEDICAL MATTERS IN THE PHILIPPINES.—LACK OF HOSPITALS, DISPENSARIES AND PHYSICIANS. — 50% OF DEATHS IN MANILA WITHOUT MEDICAL ATTENDANCE. — RINGING OF CHURCH BELLS RESTRICTED. — CHOLERA DECREASING: INSTRUCTIVE OUTBREAKS. — HEALTH REPORTS.

MANILA, Feb. 22, 1903.

MR. EDITOR: The sanitary problems here are tremendous, and the work of sanitation is hampered by racial dislike, indolence, poverty and religious superstition. The health officer in the States has something to build upon—here everything must be constructed from the very foundation. From the sanitary standpoint, the Filipino is a primitive savage. Much has been done and is being done, but the best results can be hoped for only after a number of years, as a result of a vast outlay of money and such an educational campaign as will not only alter the Filipino's mode of life but his way of looking at things. The sanitary part of the "white man's burden" over here is the heaviest part.

Funds are being raised by Bishop Brent, of the Episcopal Church in the Philippines, for the erection and maintenance of a large general hospital at Manila, in which the poor, without reference to race, can receive necessary nursing and treatment without cost. A considerable sum has already been pledged for this purpose by the American, European, Filipino and Chinese residents of Manila, Commissioner Ide of the Civil Government Board heading the list with a subscription of \$10,000. A request by those in charge of the matter has been made to the government authorities for an appropriation of sufficient funds to make up any deficiencies and enable the hospital to be started at an early date; and this will undoubtedly be done. At present, hospital facilities in Manila are totally insufficient, and there is no provision for the gratuitous treatment of the indigent. The few Spanish hospitals are poorly planned and worse equipped; and of course only the military are eligible for treatment in the army hospitals in Manila, although in the provinces these are resorted to by all American officials as the only places in which proper nursing and medical treatment can be secured. More hospitals, dispensaries and physicians are urgently needed in the Philippines. Not only many large towns but entire provinces, the latter with populations of many thousands, are entirely without physicians, hospitals or drug-stores. On the island of Mindoro, the third largest in the entire archipelago, there is not a pharmacy or a physician outside the army surgeons at the few military posts on the island. The prospect of providing proper medical attendance where little or none now exists is not good, unless district physicians are appointed and paid by the general government, as the country people are too poor to pay fees which would yield even an existence to a qualified physician and the latter would have to depend for a living upon outside support. Even in the larger towns the number of physicians is very small, probably averaging about one to every ten thousand population, and such as there are are not provided with hospital facilities for their work. As a consequence, there is much counter-prescribing by pharmacists, and large quantities of patent medicines are used. American proprietors of patent medicines are now becoming aware of the latter fact and are exploiting their preparations to a large extent by advertising posters in Spanish, Tagalog and the other native languages. This lack of physicians and hospitals is responsible for much suffering and death among the natives. Many of the army surgeons have been perfectly willing to do a charity

practice among the natives, but have been much handicapped by their lack of familiarity with the native dialects; the distrust with which any white man is regarded by the Malay; the unwillingness of the latter to submit to any surgical procedure or to interest himself in preventive medicine through sanitary reform; and the fact that medicines and supplies issued for the soldiers are not to be drawn upon for the general treatment of the natives. The qualifications of the few Filipino and Spanish doctors in the islands are not of a high order, and the Philippines furnish no opportunities for the surplus medical men of the United States for the reasons above mentioned. The Federal Party (Filipinos) has just formulated a scheme for the betterment of conditions by which, together with representatives of other professions, six medical students will be sent yearly to the United States for a two years' course of study, and have their expenses paid by this political organization. The appointees are to be selected by competitive examination from among the native candidates. This is a move in the right direction, and at least indicates an awakening by the natives to a better conception of the serious conditions now existing in the islands. Under the Spanish rule, a certain number of persons possessing a slight knowledge of medicine were licensed as "practicantes" for the treatment of the sick, but the qualifications of this class are very slight, and it is a question if the exercise of their very limited knowledge does not, on the whole, do more harm than good. These men are usually entirely ignorant of anatomy, diagnosis, surgery, midwifery, physiology and pathology, and their efforts at the treatment of disease are often misdirected. While the statistics of the Custom House in Manila show that 71 physicians arrived in the islands during 1902, these were nearly all surgeons of the army, navy or marine hospital service and could contribute but little to the treatment of the sick among the Filipinos. The great need of physicians for the natives is well shown by the fact that in December, of 791 deaths occurring in Manila, 409 occurred without any medical attendance.

The Civil Service Board in Manila is now engaged in the examination of candidates for medical positions, under the government in the islands, to create a register of approved candidates from which future appointments can be made as required. The positions will pay about \$2,000 per annum. Owing to the needs of the service, the examinations will be conducted in English only; a fact which practically bars Spanish and Filipino physicians from competition. Places in the civil medical service will come under the Civil Service rules on June 30 next, and will be filled by the appointment of candidates already approved by the Civil Service Commission at Washington. These places have up to this time been filled by selection from medical men who had been in the Philippines with the army as volunteer medical officers or contract surgeons. The Civil Service Board also announces an examination for the position of veterinarian under the insular government. Owing to the needs of the service this examination will be held in the English language only. Applicants for the examination must have had sufficient experience in laboratory work to enable them to diagnose disease by the aid of the microscope and must also possess a knowledge of protective inoculation. In view of the great prevalence of surra, glanders and rinderpest in the Philippines, the veterinary work has an important bearing upon the economic and sanitary conditions of the islands.

Several companies of native troops have lately been placed under the command of the civil authorities of the Philippine Constabulary to assist in repressing the epidemic of robbery and lawlessness which has recently started up near Manila. The medical needs of these troops are at present to be attended to by army surgeons and army hospital corps men, and supplies will be furnished from the depots of the medical department of the army for the time being. A separate medical service for the Philippine Constabulary, which now numbers about 6,000 men, is now being roughly organized and equipped on army plans. Several ex-surgeons of volunteers have been appointed as medical officers and graded as inspectors of the first class, with pay of \$1,800 per annum, and a hospital corps of natives is now being

created. Hospitals are to be established, and the islands districted and a medical officer assigned to the care of the Constabulary in each district. It is very probable that the 5,000 native troops will soon be amalgamated with the Constabulary to form an insular military force of 11,000 or 12,000 men, in which case a large medical and nursing force, with various grades, must be provided for their attendance, on the lines of the British Indian Medical Service. With a strength of 12,000 men in the native forces, the conditions here will require a medical department in connection therewith of about 75 surgeons, the same number of pharmacists, and about 300 native privates to act as nurses. Should this large medical force become necessary probably a number of army surgeons would be detailed to fill the higher grades for the work of organization and equipment, as this policy has been followed in the selection of line officers of the army to direct the organization of the combatant forces.

The Manila maternity hospital, an institution which has done much good in the past but which was about to close its doors for lack of financial support, has received a new lease of life through the efforts of the wife of Governor Taft, who has organized a society of ladies for the support of this worthy charity and is raising the necessary funds for its maintenance.

Dr. J. C. Perry of the Public Health and Marine Hospital Service, who has been in charge of quarantine matters at Manila during the past three years, has been relieved from duty and will return to the United States in the near future. Dr. Perry has established the admirable quarantine station of Mariveles for the port of Manila, and has done much valuable work in connection with the recent cholera epidemic. He is a man of energy and ability, and his transfer will be much regretted in Manila.

The ringing of the church bells of Manila at unseemly hours has caused so much annoyance and loss of sleep to American residents, and particularly to invalids, that the authorities have passed a law designed to abate this nuisance. The jangling of the bells for early mass, which is held before daybreak, was especially complained of. The new law forbids the ringing of church bells prior to 6 o'clock A.M. and after 8 P.M.

The number of cases of cholera in the islands is undergoing a steady decrease, though its presence in a large number of districts over the entire archipelago denotes the continued existence of a widespread infection. The disease is still bad in the southern islands, where the rainy season is now on, but the dry season which exists in the northern islands is having a marked effect in reducing its prevalence and apparently modifying its type. A larger proportion of cases now recover without treatment than was the fact at the outbreak of the epidemic. Only two cases developed in Manila during the month prior to Feb. 15, for which reason the quarantine of out-going transports has been discontinued.

An interesting report of a violent outbreak of cholera in a company of soldiers stationed on the island of Layte has been received in Manila. In all, 12 cases occurred, of which 11 proved fatal in spite of all treatment. The strength of the company was 85 men. Of these 12 cases, 11 developed in six days and 9 in the same 48 hours. Not only was the outbreak fulminant, but the type of the disease was very malignant, and the 11 deaths occurred in a few hours, collapse rapidly supervening upon the initial vomiting and purging. Under such conditions, but little could be done medically. The one case which recovered seemed to date its improvement from copious hot intravenous injection of saline solution, but this treatment was given in the other cases with but temporary improvement, and collapse and death soon following. All cases received stimulation by strychnin and digitalis; with external heat, friction and small doses of morphin for cramps. The troops had been warned about cholera prior to the outbreak, and quarantine had been established against the neighboring town, in which a few cases had just appeared among the natives. Investigation showed, however, that several of the soldiers who contracted cholera and apparently brought the infection into the garrison had violated these orders and gone into the town under cover of darkness, where they partook of native food

and drink. It is believed that these first cases infected some article of food served in the company mess, perhaps before they themselves manifested the symptoms of the disease. The present general epidemic in the islands has shown conclusively that only a certain proportion of those exposed to cholera infection are susceptible to the disease at any one time, and probably a much larger proportion of the company was exposed to the infection than those in which the disease developed. The outbreak also furnishes an instructive example of the fact that the disease can gain a foothold among troops only through gross carelessness or flagrant disobedience of orders, for when the company was moved to a new camp site and placed under rigid quarantine the epidemic ceased abruptly. During this outbreak, isolation and disinfection were carefully carried out in respect to the sick and the articles with which they had come into contact.

An example of the difficulties encountered in sanitary work in the Philippines is reported from the island of Jolo, where a party of sailors engaged in taking observations and making surveys was attacked by a large body of Mahomedan Moros. It appears that the cholera had caused a large number of deaths in the vicinity, and that the natives were convinced that this was due to the fact that the Americans had poisoned their wells. This belief was fortified by the fact that no case of cholera occurred in the American troops in the walled city of Jolo, where every sanitary precaution was taken, although the natives were dying by hundreds within gunshot distance of the garrison.

Much difficulty is reported in securing a sufficiency of Moro laborers for the work of construction of the new military road in Mindanao now going on, because of the great amount of sickness among them. Not only is cholera present, but large numbers of the Moros are suffering from malarial fevers, this being the unhealthy season in Mindanao. The Moros are very lightly clad, many of them wearing simply a breech clout, and they seem to suffer severely from chilling when exposed to the rains. Many of them are observed to develop a malarial paroxysm during or immediately after even a slight wetting.

The health reports for the city of Manila, for the month ending Dec. 31, give the number of deaths during that period as 753, or at the rate of 29.36 per annum. The death rate for the Filipinos was 36.83, and for the nearly 10,000 American civilians was 10.91. This higher mortality among the Filipinos was due to the great death rate of native infants and young children; 389 deaths, or more than half the total, occurring among children less than one year old. As the Americans are largely adult males of sound physical condition, the low mortality among them is readily to be understood. The following deaths occurred from the most prevalent diseases: Cholera, 23; dysentery, 20; beri-beri, 33; pulmonary tuberculosis, 66; meningitis, 32; eclampsia, 76; convulsions of children, 174; bronchitis, 68; chronic diarrhea, 20; congenital debility, 15. The high infant mortality is the most noteworthy feature of the report, and gives evidence of the great amount of work to be done in instructing the natives in the care and feeding of children. The death rate for November was 41.70, the sanitary improvement shown for December being due to the decrease in cholera. The work of sanitary inspection was vigorously prosecuted during the month by the 154 sanitary inspectors, there being 206,511 inspections and re-inspections of houses, and 37,531 of these cleaned as a result of the inspections; 24,291 yards were also cleaned. The campaign against rats was continued, 58 persons being employed as rat-catchers, besides the free use of poison; at the end of the month 1,552 rat traps were set in 1,213 houses. Besides the work on shore, 5,246 inspections of ships, cascoes, barges and other water craft were made during the month. There were 8,608 vaccinations performed in Manila, and 81,680 units of vaccine virus sent out from the vaccine farm operated by the Board of Health. The leper census up to Dec. 31 showed the presence of 3,297 lepers in the islands. Work in preparation for the new leper colony on the island of Kulion is progressing rapidly.

RECORD OF MORTALITY FOR THE WEEK ENDING SATURDAY, MARCH 28, 1903.

| CITIES. | Population Estimated, 1903. | Reported deaths in each. | Deaths under five years. | Percentage of deaths from | | | | |

Deaths reported, 3,525; under five years of age, 992; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 799, consumption 387, scarlet fever 38, whooping cough 44, cerebrospinal meningitis 6, smallpox 6, erysipelas 8, measles 26, typhoid fever 72, diarrheal diseases 69, diphtheria and croup 106.

From whooping cough, New York 6, Chicago 11, Philadelphia 5, Baltimore 2, Pittsburg 6, Providence 5, Boston 5, and Salem, Everett, Westfield and Framingham 1 each. From erysipelas, Chicago 4, Providence 1, Boston 1, Worcester 1, Lawrence 1. From smallpox, Philadelphia 2, Pittsburg 4.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending March 14 the death-rate was 17.2. Deaths reported, 4,977; acute diseases of the respiratory organs (London) 258, whooping cough 118, diphtheria 68, measles 146, smallpox 14, scarlet fever 48.

The death-rate ranged from 6.8 in Ipswich to 27.7 in Wigan; London 16.3, West Ham 16.5, Brighton 15.8, Portsmouth 13.6, Southampton 16.1, Plymouth 18.2, Bristol 16.5, Birmingham 20.6, Leicester 13.5, Nottingham 19.5, Bolton 18.9, Manchester 22.6, Salford 18.9, Bradford 20.1, Leeds 15.0, Hull 16.5, Newcastle-on-Tyne 19.2, Cardiff 12.7, Rhondda 19.6, Liverpool 22.8.

METEOROLOGICAL RECORD.

For the week ending March 28, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

| DATE | Barometer. | | Thermometer. | | Relative humidity. | | | Direction of wind. | | Velocity of wind. | | We'th'r * | | Rainfall in inches. |

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING APRIL 4, 1903.

G. E. H. HARMON, medical inspector. Detached from the Naval Hospital, Port Royal, S. C., and ordered home to wait orders.

D. B. KERR, passed assistant surgeon. Detached from the "Wabash" and ordered to the "Buffalo."

J. H. PAYNE, assistant surgeon. Detached from the Naval Hospital, Newport, R. I., and ordered to the "Wabash."

B. H. DORSEY, assistant surgeon. Ordered to the Naval Hospital, Newport, R. I.

T. H. STREETS, medical director. Commissioned a medical director from Jan. 31, 1903.

C. F. ELY, doctor. Appointed assistant surgeon March 6, 1903.

M. V. STONE, assistant surgeon. Ordered to Naval Hospital, Mare Island, for treatment.

I. N. HURD, pharmacist. Retired from active service on account of disabilities incurred in the service March 28, 1903.

A. A. HOEHLING, medical director, retired. Ordered to duty as a member of the Medical Examining Board, Navy Yard, Washington, D. C.

G. P. BRADLEY, medical director. Detached from duty as a member of the Medical Examining Board, Washington, D. C., and ordered to duty at the Naval Hospital, Washington, D. C.

R. C. DEAN, medical director, retired. Detached from duty as president of the Naval Medical Examining Board, Washington, D. C., and to duty as member of the Naval Retiring Board, Navy Yard, Washington, D. C.

F. M. GUNNELL, medical director, retired. Detached from duty at the Bureau of Medicine and Surgery, and to be president of the Naval Medicine Examining Board, Washington, D. C.

C. U. GRAVATT, medical director. Detached from duty as a member of the Naval Retiring Board and ordered to report for examination for retirement, then home to wait orders.

J. C. DEVRIES, acting assistant surgeon. Ordered to recruiting duty.

D. P. MCCORD, acting assistant surgeon. Ordered home to wait orders.

R. H. MICHELS, J. L. NEILSON, M. W. BAKER, R. SHAW, B. F. JENNESS, J. H. HALLOWAY, R. A. BACHMANN, H. F. STRINE, F. M. MUNSON, E. M. BROWN, J. P. TRAYNOR, R. E. HOYT, assistant surgeons. Detached from the Naval Museum of Hygiene and Medical School, Washington, D. C., and ordered to their homes to wait orders to sea.

L. W. SPRATLING, surgeon. Detached from the Naval Hospital, Portsmouth, N. H., and ordered to the Navy Yard, New York.

H. H. HAAS, passed assistant surgeon. Ordered to the Naval Hospital, Portsmouth, N. H.

APPOINTMENTS.

DR. DANIEL FISKE JONES has been appointed surgeon to out-patients at the Massachusetts General Hospital.

DR. WILLIAM H. SMITH has been appointed physician to out-patients at the same hospital.

DR. EDWIN A. LOCKE has been appointed physician to out-patients at the Boston City Hospital.

RECENT DEATHS.

WILLIAM GEORGE ALLEN, M.D., M.M.S.S., died in Mansfield, April 5, 1903, aged sixty-nine years.

DR. JOSEPH STANFORD AMES died at Holden, Mass., Wednesday, March 25, at the age of seventy-four years. He was born in Marlboro, Mass., in 1828, and attended the Marlboro Academy. He began his medical education at the Harvard Medical School, and graduated from the Berkshire school in 1858. In the same year he began to practise medicine in the town of Holden, and continued to exercise his profession there with credit to himself and satisfaction to his fellow townsmen for forty-five years. He was a good citizen as well as a good physician.

JAMES A. STEUART, M.D., of Baltimore, Md., died there March 27 at the age of seventy-five years. He was a graduate in 1850 of the Medical School of the University of Maryland. From 1873 he was for sixteen years health commissioner and president of the Baltimore Board of Health. In 1894 he was appointed secretary of the Maryland Board of Health, and held this office for three years.

JOHN E. SANBORN, M.D., of Melrose, Mass., died April 1 at the age of seventy-nine. He was a graduate of Wesleyan University. He received the degree of M.D. from Harvard in 1850, and for a brief period entered the practice of medicine. He later held the position of professor of chemistry and materia medica in the University of Iowa. He served as surgeon in the Civil War and recommenced the practice of medicine at Rockport, later going to Salem, and finally, in 1890, settled in Melrose.

WILLIAM LEACH, M.D., died in Vineyard Haven, April 1. He received his medical degree from Harvard in 1856. For many years he was a well-known physician at Martha's Vineyard and one of the medical examiners for Dukes County.

EDGAR PERRY, M.D., M.M.S.S., died April 7 at his home 1120 Boylston Street, Boston, aged forty-seven years, as the result of a paralytic attack. Dr. Perry was born in 1855 and was graduated from Brown University in 1880, later receiving the degree of A.M. from the same institution. From 1880 until about 1894 he was actively engaged in newspaper work in various cities. He was graduated from the Harvard Medical School in 1898, and soon thereafter established a private hospital in Boston, which is in successful operation. He was twice married, and leaves a widow and three children.

SOCIETY NOTICE.

NEW ENGLAND HOSPITAL MEDICAL SOCIETY. — A regular meeting of the society will be held at 3 Park Street, Boston, Mass., on Thursday, April 16, 1903, at 7.30 P.M. The meeting will be in charge of the Section on Ophthalmology; Dr. Ella L. Dexter, chairman.

Paper — with presentation of patients; "Trachoma; A Menace to the Community"; by Dr. Ella L. Dexter.

Discussion opened by Drs. Ella L. Wylie and Louise P. Tingley. Presentation of specimens, by Dr. Clara J. Alexander.

DR. AGNES C. VIETOR, Secretary,
Trinity Court, Boston.

BOOKS AND PAMPHLETS RECEIVED.

Patent and Proprietary Medicines as the Cause of the Alcoholic and Opium Habit or Other Forms of Narcomania, with Some Suggestions as to how the Evil may be Remedied. By Lewis D. Mason, M.D., of Brooklyn, N. Y. Reprint. 1903.

An Operation for the Radical Cure of Aneurism Based upon Arteriorrhaphy. By Rudolph Matas, M.D., of New Orleans, La. Reprint. 1903.

Climates and Health Resorts in the Dominion of Canada. By Guy Hinsdale, M.D. London. 1902.

The Practical Medicine Series of Year Books, comprising ten volumes on the year's Progress in Medicine and Surgery. Issued monthly. Under the general editorial charge of Gustavus P. Head, M.D. Vol. IV. Edited by Emilius C. Dudley, A.M., M.D., and William Healy, A.B., M.D. Illustrated. March, 1903. Chicago: The Year Book Publishers.

Gastrojejunostomy with the McGraw Elastic Ligature, for the Relief of Gastroptosis. By H. O. Walker, M.D., of Detroit, Mich. Reprint, 1903.

Causes of Epilepsy in the Young. By A. Jacobi, M.D., LL.D., of New York. Reprint. 1902.

Peribronchitis and Interstitial Pneumonia. By A. Jacobi, M.D., LL.D. Reprint. 1903.

Portal Anastomosis: with Report of a Case. By Daniel H. Craig, M.D., Boston. Reprint. 1903.

Permanent Suprapubic Drainage for Advanced Tuberculosis of the Bladder. Report of a Case at End of Five Years. By Charles A. Powers, M.D., of Denver, Colo.

Original Articles.

A CASE OF INTERSCAPULO-THORACIC AMPUTATION FOR SARCOMA OF THE BRACHIAL PLEXUS.

BY F. B. LUND, M.D., BOSTON.

Summary. HISTORY OF A CASE OF SARCOMA OF THE BRACHIAL PLEXUS FOLLOWING INJURY — ATTEMPTED REMOVAL WITH RUPTURE OF AXILLARY VEIN — SUTURE OF VEIN — SUBSEQUENT INTERSCAPULO-THORACIC AMPUTATION — RECOVERY — NO RECURRENCE AFTER THREE MONTHS — PATHOLOGICAL REPORTS — REMARKS ON THE OPERATION AND POINTS IN TECHNIQUE — REVIEW OF POINTS OF INTEREST IN THE CASE.

T. D., age, forty years, a grocer's clerk, of Irish nationality, was referred to Dr. G. H. Monks' service at the City Hospital on August 19, 1902, for an exploratory operation with reference to the condition of the left median nerve. He was recommended for operation by Drs. W. N. Bullard and J. J. Thomas, who had had him under observation at the Out-Patient Department for Diseases of the Nervous System, and by whose courtesy the writer is able to append the following history kindly furnished from the Out-Patient Records by Dr. Thomas:

First seen on July 25, 1902. Eleven months ago a heavy case fell upon him, striking the left arm over the deltoid and crushing his arm against the side of a car, and also striking his knee. He was laid up, with the knee on a splint, for eleven weeks. The knee is now nearly well, though slightly stiff. It is worse in damp weather and after rest. At the time of his injury the arm was painful, but he did not pay much attention to it. The arm has been growing steadily worse, with darting pain in the radial side of the hand and in the forearm which has lately prevented sleep. The hand has grown weak and shrunken on the side where the thumb is, the patient states. The pain is better if he uses the hand. There is some numbness and pricking sensation. No tenderness has been noticed.

The physical examination showed a well-nourished, muscular man in excellent general condition. There was marked atrophy of the left forearm, excepting the upper part on the radial side. Marked atrophy of the thenar eminence and slight atrophy of the dorsal interossei. Sensation impaired over the whole of the forearm and hand. Grasp — right, 30; left, 22. Motion of the left upper extremity is possible, except that the thumb and index finger cannot be closed. Elevation of the shoulder not so good on the left as on the right. Considerable weakness in all movements of left arm. This is said to have been produced by a cut with glass, one week ago. Spine, normal. Heart, negative. Knee jerks, normal. No ankle clonus.

Electrical examination. — The deltoid and triceps react normally to the Faradic current, while the triceps shows a diminished irritability. The flexor digitorum, flexor carpi radialis, the short flexor of the thumb, opponens, and abducens pollicis and the first two lumbricales show no reaction to the

Faradic current. The same muscles show a quick twitch to the galvanic current, and no reaction of degeneration.

Aug. 1, electrical examination shows quantitative change to Faradism. No reaction of degeneration. The flexor carpi ulnaris shows the same changes as the group given above. Pain was severe, and on the 18th of August he was recommended for admission to the hospital. The house record gives the following physical examination: Left arm showed atrophy and nearly complete paralysis of the muscles supplied by the median nerve, with anesthesia of palmar surfaces of index, middle and part of ring fingers and portion of thumb. Under treatment with hot air, baths, massage, etc., no improvement resulted, and an exploratory operation was advised, but refused, and on Aug. 30 he was discharged.

On Sept. 6 he returned to the hospital on the advice of Dr. Thomas, who had discovered a tumor in the left axilla. The mass in the axilla was rounded and irregular in surface, strongly suggesting a mass of hypertrophied axillary glands. It was hard, somewhat movable and very tender on palpation, which latter fact, combined with its recent appearance, suggested strongly an inflammatory origin.

Under ether the writer made an incision along the posterior border of the pectoralis major, exposing the tumor, which was found to be dark purple, very vascular, elastic, friable, and on enlarging the incision so as to expose the entire axilla, it was found to extend upward from the point where the median nerve is formed by the junction of the trunks from the outer and inner cords of the brachial plexus along the axillary artery and vein, and to be intimately adherent to these structures and to the brachial plexus. The largest mass, and apparently the primary one, arose from the origin of the median nerve from the junction of the cords as described above. An attempt was made to dissect the growth free from the axillary vessels and remove it, but after the tumor had been followed up two inches or more, in separating the axillary vein, which here described an S-shaped curve in front of the tumor, the vein was torn, and in attempting to grasp the rent with the forceps it was torn still further. By compressing the vein with the finger above and below the rent, the blood was easily excluded and the rent closed by three silk sutures passed through the outer coats of the vein with a fine, curved, round needle. On allowing the blood to re-enter the vein, the suture was found to hold. A large piece of the growth was removed for microscopic examination, the hemorrhage from the cut surface of the growth stopped by gauze packing, and the wound sutured.

The drainage was removed in forty-eight hours, and the wound healed aseptically throughout. Microscopic examination showing the growth to be sarcoma, the patient was advised to undergo an interscapulo-thoracic amputation. He was in constant pain from the involvement of the brachial plexus in the growth, and his arm was useless. He refused operation, and left the hospital on Sept. 26.

On Oct. 8 he returned for operation on advice of his physician, Dr. Devine. Since leaving the hospital he had suffered severe pain in the arm, from which he had had temporary analgesic relief. He had had x-ray treatment, one or two exposures.

Examination showed that the axillary tumor had very rapidly increased in size. A large mass, the size of a mandarin orange, bulged forward the pectoralis major and had appeared since the previous operation. The arm and hand were slightly edematous. The motions of the shoulder joint were much limited and very painful. Paralysis and atrophy were the same as previously noted. The patient was very anxious for any form of relief.

On Oct. 10 the interscapulo-thoracic amputation was performed as follows: The patient was placed on his back near the edge of the table, with a narrow pillow between the shoulder blades. An incision was made over the clavicle from a point near its articulation with the sternum to a point within two inches of the acromion. The incision was carried down through the periosteum, which was stripped off around the whole circumference of the bone. About two and a half inches of the middle of the clavicle were resected with a chain saw. The subclavius muscle and several layers of fascia were divided vertically. The upper half of the pectoralis major was divided from above downwards, opposite the center of the clavicle. By blunt dissection, partially assisted by the cephalic vein as a guide, the subclavian artery and vein were identified and isolated. After ligation of the artery with a double ligature of heavy silk, the distal portion was clamped and the vessel divided. After elevating the arm to allow as much blood as possible to drain from it, the vein was ligated and divided in a similar manner. The suprascapular artery and vein, which were exposed in the base of the neck, were ligated and divided. The arm was abducted and the incision carried downward and backward across the axilla to the anterior border of the latissimus dorsi, dividing the pectoralis major and minor muscles about their middle. Several small vessels originating below required ligature. The cords of the brachial plexus now stood out prominently under some tension. Each cord was injected with about 10 minims of a $\frac{1}{4}\%$ solution of cocaine, and divided. The pulse was unaffected by this procedure. The arm was now brought across the body and elevated, putting the scapular muscles on the stretch. The first incision over the clavicle was connected with the lower end of the second incision at the anterior border of the latissimus dorsi by an incision passing downward and backward over the middle of the spine of the scapula. The skin flap was caught with double hooks and turned back; the levator anguli scapulae, trapezius, rhomboidei and serratus magnus muscles were rapidly divided and the extremity removed. The posterior scapular artery was easily caught and ligated when divided. A number of small vessels in the muscular tissue and posterior skin flap required ligature, and also one or two small arteries accompanying the cords of the brachial plexus. The flaps were easily brought together and adjusted without tension with interrupted silkworm gut and a few coarse silk sutures. A small drain was placed in the lower angle of the wound.

The pulse, which had not quieted down from the administration of the anesthetic, remained at 130 to 136, and of good quality, and did not vary in rate or character during any of the operative procedures.

He made a good recovery from the ether. There

was little vomiting and almost no pain except during the first night, when morphia was required. On Oct. 12, when the wound was dressed, it was found to be clean, and there was no redness or tenderness. The wick was removed on that date.

On Oct. 16 the patient was very comfortable, suffering only occasional pain in the wound.

On Oct. 20 the stitches were removed. The wound healed by first intention.

On Oct. 23 the patient's general condition was excellent. The wound was healed, and caused him no pain. He was discharged on that date.

The patient was shown at the meeting of the Boston Medical Library in February, 1903. He was then in excellent physical condition, had suffered no pain, and was delighted at the result of the operation. There was no evidence of recurrence, and he had gained considerably in weight.

The appended photograph of the patient was taken ten days after the operation. The old scar

FIG. 1.

running downward at right angles to the amputation scar is a part of the axillary incision made at the first operation.

The following description of the gross specimen was furnished by Dr. Brinkerhoff:

Specimen consists of left arm, scapula and outer two thirds of clavicle. In the axilla, on the upper and inner aspect of the arm, is a partly healed wound, 5 cm. in length. In the axilla are two tumor masses. The first consists of a more or less spherical mass, 5.5 x 8 x 5 cm. This mass rises to, and invades, the coracoid process of the scapula. This mass is more or less definitely encap-

ulated. On section the cut surface yields much bloody fluid, its general color is dark red. The mass is subdivided by numerous fibrous bands, which divide it into smaller masses, 1.0 to 1.5 cm. in diameter. These smaller masses are exceedingly soft, and vary from a dark red to a mottled pink and red color. The second tumor lies immediately under the skin wound above described. It is irregularly fusiform in shape, its longest axis being parallel to the course of the median nerve. The tumor is not sharply circumscribed, and measurements of it are therefore approximate (9 x 6 x 7 cm). This mass is of firm consistence, presenting on section irregular areas from 0.5 to 2.0 cm. in diameter, which are a little softer than the firm fibrous tissue in which they lie imbedded. The fibrous stroma is grayish yellow in color. The nodules are sometimes a translucent gray, sometimes speckled over with pin-point to pin-head sized red, or red-brown, irregular areas.

The tumor mass is in relation with the nerve trunks at their exit from the brachial plexus. The internal cutaneous, the musculo-spiral, the ulnar and musculo-cutaneous nerves all lie either close to, or are partly surrounded by, the tumor mass. These nerves, however, show no macroscopic evidence that the tumor has invaded their sheaths. The median nerve enters the tumor mass and emerges from it.

Where the internal branch of the outer cord of the brachial plexus enters the tumor mass, its fibers are spread apart to include a reddish-brown nodule, 0.5 cm. in diameter. The junction of the outer and inner roots of the median nerve takes place in the upper part of the tumor mass. A series of sections through the tumor, perpendicular to the course of the median nerve, show the nerve only for a short distance after its entrance and before its exit. The brachial and axillary artery and vein pass through the tumor mass, but appear to be unaffected. Portions of the internal-cutaneous, musculo-spiral, median, ulnar and musculo-cutaneous nerves from beyond the tumor are preserved in formol. Portions of both tumors preserved in Zenker's fluid.

MICROSCOPICAL EXAMINATION BY DR. J. J. THOMAS.

Sections taken from the tumor, from the smaller, soft tumor, from the musculo-cutaneous, ulnar, internal cutaneous, musculo-spiral and median nerves, and from the axillary artery were stained with eosin and methylene blue, by Marchi's method, by Weigert's myelin sheath stain, and by Mallory's connective tissue stain.

Sections of the tumor show it to be a mass with fairly definite connective tissue capsule. At one point at the border of the tumor is seen the internal cutaneous nerve. This is not infiltrated by the tumor, nor has this penetrated between the nerve bundles into the endoneurium. The nerve bundles are shrunken, and show considerable edema, there being a space between the endoneurium and the nerve fibers. The nerve fibers are degenerated and show no evidence of myelin sheaths, though the remains of these are seen faintly stained, and rarely an axon is seen still preserved. The tumor itself shows but few blood vessels, and is composed of a mass of rather large cells, quite irregular in shape, with homogeneously staining protoplasm, occasionally showing vacuoles and large nuclei, generally oval in shape, with a coarse meshwork of chromatin. In many nuclei one or several dots of chromatin are seen. A few cells, with two or more nuclei, are occasionally seen. Cells with nuclei in mitosis are common, being seen in almost every field. The sections stained with Mallory's connective tissue stain show a considerable amount of connective tissue fibers between the tumor cells, as well as surrounding the tumor mass. Fairly numerous small hemorrhages are seen scattered throughout the tumor, and in some places about these the tumor cells appear necrotic, staining poorly, but in general the cells are extremely well preserved. In the connective tissue about the tumor are seen occasional areas containing considerable free blood pigment. Here and there in the connective tissue about the tumor, and in the epineurium between the nerve bundles, are seen areas of infiltration with round and plasma cells, and occasionally similar small areas of infiltration are found in the tumor substance.

The small, soft, red tumor mass is composed of tumor

cells similar to those of the large tumor described above, but with numerous large hemorrhages scattered throughout its substance. Sections of the inner root of the median nerve show no nerve fibers whatever, but merely connective tissue with two or three small masses of tumor cells similar to those described, and several areas of hemorrhage. Section of the outer root of the median nerve where it passes over the large tumor show the tumor as previously described, and at its border the nerve bundles, which, like those of the internal cutaneous nerve, show complete atrophy of the nerve fibers, with marked edema, and areas of infiltration with round cells in the epineurium. Here in the epineurium, between the bundles of nerve fibers, are seen two or three areas infiltrated with the tumor cells, and in two or three places the endoneurium is completely penetrated, but no cells are seen between the nerve fibers.

Sections of the artery, containing a clot, show no infiltration with tumor cells, but considerable thickening of the intima, more marked at one side of the vessel, and several small areas of infiltration with round cells about the small blood vessels of the adventitia.

The sections of the median nerve and those of the internal cutaneous nerve show almost complete atrophy of the nerve fibers; most sections showing no fibers with retained myelin sheaths, and the sections stained by Marchi's method show practically no drops staining with the osmic acid in the nerve bundles.

The sections of the musculo-cutaneous, ulnar and musculo-spiral nerves show marked degeneration of the nerve fibers; approximately one third to one half of the fibers, however, still retain the myelin sheath. Sections from all these nerves show considerable acute degeneration of the myelin sheaths still present; from one quarter to one third of them showing drops stained by the osmic acid.

ANATOMICAL DIAGNOSIS.

Large cell sarcoma.

Atrophy and infiltration by tumor growth of median and internal cutaneous nerve.

Degeneration of musculo-cutaneous, ulnar and musculo-spiral nerves.

THE OPERATION.

The interseapulo-thoracic amputation was performed first by Twitchell in Keene, N. H., in 1838, and by McClellan in the same year. Recovery resulted in both cases. In 1900 Fowler¹ collected 72 cases in which primary interseapulo-thoracic amputation was performed for malignant disease of the humerus, with eight deaths resulting from the operation, either from hemorrhage, shock or infection,—a mortality of about 11%. Ashurst in 1881 collected 51 cases in which the operation had been done for various causes, with a mortality of 25.5%, and in 1895 added 39 cases with a mortality of 24.3%. These figures have little value in reference to the advisability of operating in any given case, as they include patients in all kinds of general condition, and with more or less extensive invasion of the disease. Given a patient in good general condition, in whom the disease has not extended so as to involve the chest wall or the subclavian vessels, and the operation seems to the writer hardly more dangerous than any other major amputation.

The only part of the operation requiring special attention to technique is the ligation of the subclavian artery and vein, which should obviously be done with great care to avoid hemorrhage from wounding the veins, or air embolism. After this is accomplished the operation is simplicity itself, and is almost bloodless, the only artery of any size which

¹ Annals of Surgery, January, 1902.

must be caught in the wound being the posterior scapular.

The method followed by the writer corresponds in its main features to that advocated by Paul Berger in his monograph of 1887, and has been sufficiently described in the account of the operation.

The special points in the technique which the writer would insist upon as important are, first, the ligation of the artery before the vein, then the elevation of the extremity, so as to empty it as far as possible of blood before ligating the vein. The artery and vein in this instance were both secured by two ligatures of coarse twisted silk, tied about one fourth of an inch apart, to avoid the possible hemorrhage from the slipping of a single ligature, and the vessels were divided one fourth of an inch distally to both, a clamp being placed upon the vessels to avoid hemorrhage from their distal ends.

In this case the man's excessive muscular development made the wound required to reach the vessels very deep, and the operator was greatly aided by section of the clavicular and upper sternal portion of the pectoralis major. In the deep wound the artery was entirely covered by the distended axillary, cephalic, suprascapular, and superior intercostal veins, which had to be very carefully freed by blunt dissection. This procedure was made much simpler and safer by section of the muscle, which the writer would recommend to others in similar cases.

The disarticulation of the clavicle at the sternal end, as advocated by LeConte,² seems to the writer advisable only in case such division of the muscles fails to give enough room, as it sacrifices more of the attachments of the sterno-mastoid and involves the risk of wounding the innominate vein.

The second point in the technique which is worthy of note is the cocaineization of the trunks of the brachial plexus before division. The physiological blocking effect of cocaine when injected into the nerves of the extremities proximal to their point of section has been so conclusively shown by the admirable experimental researches of Dr. George Crile³ as to leave little doubt of its value in the prevention of shock, and to lead to its general adoption. Certainly in this case the section of the nerves was attended by no effect on the pulse perceptible to the examining finger. It is to be regretted that the effect on blood pressure was not noted by the use of the Riva-Rocci apparatus. Cocaineization of the nerve trunks is a very simple procedure, as it requires only a few seconds to inject a few drops of the solution into the loose tissue of the nerve trunks, which quickly bulges the injected portion into an edematous translucent bulb, which should entirely surround the nerve, thus showing that all the fibers have been brought in contact with the solution.

A word as to the indications for operation. The principal indications are:

(1) In the majority of cases of malignant disease of the humerus, and especially any that involve the tissues about the shoulder joint.

(2) In malignant disease in the axilla involving the axillary vein, which cannot be ligated without sacrificing the arm.

(3) In extensive injuries, usually machinery accidents to the arm, shoulder and scapula, in which the scapula has been partially or completely torn away, or the skin over the deltoid has been destroyed so that it is not available for the covering of an ordinary shoulder joint amputation.

The case presents several points of interest, not the least of which is the apparently close relation in time between the development of the tumor and an injury to the arm. The early paralysis of the median nerve, and the fact that that nerve and the cords which form it were actually involved in the growth while the other nerves of the brachial plexus were affected simply by pressure, point probably to the tumor as of primary origin in that nerve.

The attempted removal of the axillary mass was valuable as an exploratory procedure, giving an exact idea of the nature and limits of the tumor, and of the extent of the operation necessary for its removal. Notable in connection with this operation was the ease with which it was possible to close the rent in the axillary vein by suture.

The rapid growth of the tumor, and its juxtaposition to the great vessels at the base of the neck and thorax, would probably have rendered any other treatment than that by the operation adopted unsuccessful. Even should recurrence take place, the patient has been rewarded by a complete freedom from pain for a considerable interval.

THE DIAGNOSIS OF GONORRHEAL URETHRITIS.

BY ALFRED H. GOULD, M.D., BOSTON,

*From the Clinico-Pathological Laboratory,
Massachusetts General Hospital.*

THE introduction of the gonococcus into the urethra rarely causes any symptoms for the first twenty-four hours. After this period a sense of irritation and a moisture at the meatus may be observed, which increases in intensity until, at the end of two to four days, it has developed into a purulent discharge.

The length of the incubation period is usually fairly constant, but occasionally may show wide variation. It depends upon the rate of production of, and the susceptibility of the urethra to, the toxin.

The toxin is elaborated by the living, and is contained in the dead, bacterial bodies (Christmas). The production of toxin probably commences at once in the urethra, but not in sufficient quantity to irritate the urethra until a number of colonies have developed. From this assumption it follows that gonococci may be present in the urethra before there is any pus formation, and the recognition of their presence at this time allows measures to be taken to head off an acute urethritis. The presence of the gonococci may be recognized by the examination of the urine by means of coverglass preparations and by cultures. Stained preparations of the sediment will show the presence of different bacteria. The predominating organism will be a coccus that decolorizes by Gram, and which frequently is arranged in tetrads. Absolute proof that this prevailing coccus is the gonococcus can only be established by culture.

² *Annals of Surgery*, October, 1902.

³ *Problems Relating to Surgical Operations*, Philadelphia, 1901.

The writer has, however, not been able to obtain a growth of the gonococcus at this stage.

After the urethritis is thoroughly established, the identification of the gonococcus is easy on slide and by culture. It is of interest, however, to study the changes which take place in the pus cells during this period. In the earliest stages the gonococci are extracellular. The presence of pus at once gives the gonococci an unlimited medium in which to multiply.

They invade or are taken up by these cells and rapidly proliferate. The leucocytes at once begin to show degenerative changes. The nuclei increase in size and react to stains less readily. This brings out the internal structure of the nucleus so that

of suspected early urethritis. Next in importance to the early examination for diagnosis is the late examination of the sediment for prognosis. There are many cases where it is necessary to ascertain whether or not a patient is cured, or whether an intractable gleet is due to the gonococcus or to other causes.

The demonstration of gonococci in a very chronic discharge is repeatedly baffling, for two reasons: First, the organism may not be present in the discharge at the time of examination, or, finally, the gleet may be due to some other bacterium.

The gonococci can be cultivated in a fair proportion of the chronic cases, if they can be found in the sediment. A successful cultivation is assisted

GOULD-URETHRITIS.

FIG. 1.—Sediment stained by Gram; early urethritis; no pus formation. Prevaling organism a coccus arranged in tetrads, decolorizing by Gram.

FIG. 2.—Gonococci inside nuclei of leucocytes.

FIG. 3.—Same as Fig. 2.

into a chronic condition, when the urine is more or less clear and contains shreds. The value of shreds as a rough method of gauging the urethral condition is great, but is only half understood by most practitioners. Shreds indicate fairly exactly about how much pus is floating free in the urine. This pus may not be of sufficient quantity to cloud the urine, but it will form a definite sediment when centrifugalized. The microscopical examination of the shreds themselves is not important in the demonstration of the gonococci, for the gonococci are rarely found in the shreds but in the pus cells, which are floating free in the urine. The prevailing idea that the gonococci are to be sought for in the shreds is erroneous. It is important to notice whether or not the shreds consist of pus. The shreds, which are heavy and sink to the bottom of the urine glass, are made up of pus, and these are associated with the largest quantity of free pus in the urine. The meaning of shreds, therefore, is a secondary one in the study of urine. The general sediment contains practically all the pus and bacteria.

The writer has pointed out the assistance that may be given by an examination of the sediment in cases

of suspected early urethritis. The most practical and the most easily obtainable is hydrocele fluid. It contains no fibrin ferment and forms no clot. This fact renders it less open to contamination. It is essential to collect the fluid under rigidly aseptic precautions in test tubes. After twenty-four hours in the thermostat, the infected tubes can be thrown out and the remainder kept in the ice chest until ready for use. Gonococci grow both in liquid and in solid media easily. If liquid media is used the hydrocele fluid is mixed in equal parts with bouillon. Agar-agar is employed for solid media in strengths from 2% to 2½%. The reaction of the medium should be about + 1 (scale of the American Public Health Association). The growth upon strongly alkaline media is rich and rapid. It is short-lived, and quickly shows degenerative forms. Gonococci can be cultivated in reactions varying from + 1.5 to — 2.0.

The agar is melted, cooled to 40° C. and mixed while liquid with the hydrocele fluid in the proportion of 2 agar to 1 hydrocele. The tubes are then slanted and allowed to remain for twenty-four hours. As much hydrocele may be put in as the

agar will stand, but too great dilution will cause the slant to slump when put into the thermostat.

The writer wishes to express his obligations to the gentlemen of the Surgical Staff of the Out-Patient Department of the Massachusetts General Hospital, and to Dr. Gardner Allen of the Boston Dispensary, for their courtesy in furnishing material for this work.

The photo-micrographs were taken by Mr. Louis S. Brown of the Clinico-Pathological Laboratory of the Massachusetts General Hospital.

CREAM FOR THE HOME MODIFICATION OF MILK.¹

BY CHARLES W. TOWNSEND, M.D., BOSTON.

It is, of course, a trite observation that if we dilute cow's milk so as to obtain the proper amount of albuminoids for infant feeding we obtain too weak a fat—hence the need of starting with cream, and cream of a known percentage.

There are various ways of obtaining this cream, all of which have their advocates, and the importance of the subject has led me to try to find the most accurate, and if possible the simplest, method for obtaining this cream. In furtherance of this end the analyses of over a hundred specimens of cream with the Babcock tester have been made for me by Dr. Wilder Tileston, for whose careful and conscientious work I am greatly indebted. To ensure accuracy, two separate analyses were made of each specimen.

The methods for obtaining cream for infant feeding may be set down as follows:

- (1) Cream by the centrifugal process.
- (2) Gravity cream or top milk obtained by siphonage.
- (3) Gravity cream obtained by dipping off the top.
- (4) Gravity cream obtained by pouring off the top.

(1) CENTRIFUGAL CREAM.

The advocates of this cream for the modification of milk think that the process has no detrimental effect on the cream, and that the supposed accuracy of percentage is of great advantage in making up the modifications. The following table is of nine specimens of centrifugal creams, bought in the open market of several responsible firms. In each case the cream was stated to have the percentage given in the first column, and the results of the analyses given in the second column show, with few exceptions, considerable variation—greater in most cases than, as will be seen later, is found in gravity cream obtained at home.

Clinical experience may, of course, be misleading, but must be the final test; and there are many, myself among the number, who have failed to obtain as satisfactory results with centrifugal as with gravity cream in the feeding of infants.

TABLE OF PERCENTAGES OF CENTRIFUGAL CREAM.

| Per cent stated. | Per cent found. |
|------------------|-----------------|
| 10..... | 15.0 |
| 16..... | 14.1 |
| 18..... | 16.9 |
| 20..... | 17.0 |
| 20..... | 20.2 |
| 20..... | 16.5 |
| 40..... | 34.3 |
| 40..... | 35.3 |
| 40..... | 35.3 |

(2) GRAVITY CREAM OBTAINED BY SIPHONAGE.

A glass siphon filled with sterilized water is introduced into the bottle or can after it has stood six to eight hours and the lower milk drawn off, leaving the cream. In applying the test of simplicity to this method, it is evident to any one who has siphoned milk himself that the process is not a simple one, or one that can be easily and safely performed by an untrained and ignorant hand. To keep the long glass tube clean and sterile, to introduce the tube filled with sterile water through the cream, to draw off this water into one vessel, the milk into another, and to stop the rapid flow of the siphon at exactly the right point, and withdraw it through the cream, is not an easy process. I have known of a rubber tube being advocated as simpler for siphonage, which reminds one of the filthy condition of the interior of rubber tubes used in the old-fashioned feeding bottle, and suggests suction as a method for starting the siphonage.

As to accuracy, if the flow is stopped at exactly the right spot, the analyses obtained from different bottles of the same milk vary but little, but of course considerable variation would occur if the flow were stopped too soon or too late. Thus the analyses of the cream obtained by siphonage from two bottles of the same milk (upper 8 oz.) was 13.5% and 13.7%, and in another case 12.9% and 12.5%.

The method is, therefore, an accurate one, but one requiring considerable intelligence to perform accurately and safely.

(3) GRAVITY CREAM OBTAINED BY DIPPING OFF THE TOP.

Dr. Chapin's dipper,² made either of tin or aluminum, can be used for this purpose. This is a much simpler and easier process than siphonage; and the dipper is safer, as it is more easily kept clean. As to accuracy, it was found that a considerable variation could be obtained, depending on the care with which the dipper was lowered into the bottle. Thus the upper 8 oz. dipped off with great care in one case showed 14.2 of fat; the same milk dipped off from another bottle carelessly, although measured accurately, showed 13.6. In another case the analyses were 16.1 and 14.3%, respectively,—a variation of .6 in the first case and 1.8 in the other.

This variation is not great, and can be avoided by almost any one who is willing to take pains to lower the dipper slowly as it fills, and not to plunge it carelessly below the surface.

¹ Read at the meeting of the Boston Medical Library, Feb. 23, 1903.

² "Home Modification of Cow's Milk for Infant Feeding." H. D. Chapin, New York Med. Journ., Nov. 4, 1889.

(4) GRAVITY CREAM OBTAINED BY POURING OFF THE TOP.

This is a method I have used for a number of years, and with excellent results. Its very simplicity, requiring no instruments, either of glass, tin or aluminum, to keep clean, fails to appeal to some minds. If it is accurate, that is, if with two or more specimens of the same milk set under the same conditions, we can obtain the same percentage of fat, if we can obtain a sufficiently high percentage of fat, and also varying percentages of fat depending on the amount poured off, it seems to me this simple method should take precedence of all others. There are no instruments to be bought, none to endanger the cream from improper care, no process more or less elaborate to be taught, and no variations in the methods of carrying out the process. Any one can pour off milk up to a given measured mark in a graduate or glass, and do it accurately. I have poured slowly and carefully, and again hurriedly and carelessly, but in each case pouring off the amount accurately, and have found hardly any variation in the percentages. Thus pouring off the upper 8 oz. with care, I have obtained 10.8% of fat, and carelessly pouring off the same amount from another bottle of the same milk, the analysis was 10.6; at another time the percentages were respectively 10.1 and 10.2, a variation of only .2 and .1%. This method is, therefore, accurate as well as simple.

In all these cases of gravity cream the milk has stood eight hours.

The fact that in pouring off, some of the thin, lower milk is seen to flow off at the same time need not disturb us, provided we get a sufficiently high percentage of fat. As will be seen by the following table, almost any percentage can be obtained by varying the amount poured off. Although milk from different sources varies considerably, and will also vary with the time of year, it is possible to obtain surprisingly little variation from day to day, if the dairy is well and honestly managed. By this is meant not only that the internal arrangements of the dairy are good, but also that the milk comes only from the dairy, and its volume is not made up irregularly by milk from inferior farms or from railroad milk.

It will be seen that in twenty-eight examinations made of the upper 8 oz. poured from the quart in July, August, September and October, months when considerable variations take place in the food of the cows, the average analysis was 10.8%, with an extreme variation of 9.8 on one side and 11.9 on the other. This was milk from a herd of eighty or ninety cows kept under model conditions. The milk was delivered to me as one of the regular customers without any knowledge on the part of the dairyman that examinations were being made. Doubtless the milk varies more than this at other times of year, and from different milk supplies, indeed, I have found the percentage of the top quarter poured off as high as 12.6 and as low as 8.1; but these examinations show that we can feel sure of considerable uniformity from day to day, from the same dairy.

I have found the average percentage of the upper 8 oz. obtained by the Chapin dipper or the siphon

to be 2 to 3% higher than that obtained by pouring off the upper 8 oz. The following table shows the percentage of fat as obtained by pouring off varying amounts of top milk:

| Number of examinations. | Amount poured off from a quart after standing 8 hours. | Extremes per cent. | Average per cent. |
|-------------------------|--|--------------------|-------------------|
| 5 | 3 oz. | 19.9 — 23.3 | 21.7 |
| 9 | 6 oz. | 13.2 — 15.2 | 14.0 |
| 28 | 8 oz. | 9.8 — 11.9 | 10.8 |
| 9 | 12 oz. | 7.6 — 8.8 | 8.1 |
| 6 | 16 oz. | 5.4 — 6.9 | 6.5 |

For practical purposes, then, we can assume that in pouring off from the quart, after standing eight hours, the upper 3 oz., we obtain a 22% cream, the upper 6 oz. a 14% cream, the upper 8 oz. a 10% cream, the upper 12 oz. an 8% cream, and the upper 16 oz. a 6% cream.

Let us see how much difference in the analysis of the modification it would make if we assumed that the cream was 10%, and it should really be 12% or 8%. Following the rule which I have formulated,³ each ounce of 10% cream, in a 20-oz. mixture, represents .50% of fat, .20% of albuminoids and .20% of sugar; and each even tablespoonful of sugar of milk added to this mixture raises the percentage of sugar 2%, and taking 4 oz. of top milk, 15 of water, 1 of lime water and 2 measures of sugar of milk, we would have, if it were 10% fat, fat 2, sugar 4.80, albuminoids .80; if it were 8% fat, the final modification would be 1.6% fat; if it were 12% fat, it would be 2.4% fat.

Infants are not cast in the same mold — they are very unlike; and a certain amount of clinical experimentation is needed in every case, and with that an approximately accurate knowledge of the percentage is all that is necessary. Analyses of mothers' milk show much greater variations from day to day, and from hour to hour, and even during the course of one nursing, than is shown in the mixed milk obtained daily from the same herd of cows. The more cows, the greater the uniformity, as individual peculiarities are lost. The albuminoids and sugar of cows' milk I have not considered here, as these constituents vary so little we can, for practical purposes, regard them as constant.

If with a supposed 10% top milk we obtain symptoms of too much fat, it is an easy matter to pour off more of the top milk. Occasional examinations of the milk with the Babcock machine are of great advantage, but not an absolute necessity. In feeding delicate babies, or those whose digestion has been entirely upset, one should begin with a very weak modification of all the constituents, and then gradually advance by very small steps. In this way the dangers from variations in the richness of the cream can to a large extent be avoided. The more the cream is diluted, as in the case of delicate babies, the more the error is diluted also.

³ Home Modification of Milk. C. W. Townsend, Boston Med. and Surg. Journ., March 23, 1899; and *ibid.*, Oct. 11, 1900.

CONCLUSIONS.

(1) Centrifugal cream is probably less desirable for infant feeding than gravity cream. As obtained from dealers it is often far from accurate in percentage.

(2) Siphonage for obtaining gravity cream is an accurate method, but one requiring considerable skill to perform accurately and safely.

(3) Dipping off the top milk is an accurate and safe method if reasonable care is used.

(4) The method for obtaining gravity cream by pouring off the top is very accurate and extremely simple. There is no instrument to be bought and kept clean. By this method it is possible to obtain cream of any desired percentage up to 26%.

(5) To ensure perfect accuracy, frequent examinations with the Babcock machine are required; but for practical purposes this is not necessary, provided the mixed milk from a well-regulated dairy is obtained.

VARIATION IN THE COMPOSITION OF HUMAN MILK.¹

BY PHILIP P. SHARPLES AND EUGENE A. DARLING, M.D., CAMBRIDGE, MASS.

ANALYSES of human milk have been numerous, but few attempts have been made to carry out a series of analyses in a systematic manner. The purpose of the present investigation was to provide data from samples numerous enough to sink the effect of any individual sample in the average of all the samples.

Collection of samples.—The samples were collected under as uniform conditions as possible. After the child had suckled in the morning nursing for a few minutes, a sample of about 1 oz. was drawn by the breast pump. The sample was forwarded to the laboratory in a mailing case. The analytical work for all except a few of the samples was begun within a few hours of the collection of the samples. Some, however, were preserved until the succeeding day with a drop of formalin.

The methods of analysis used were as follows:

Total solids.—The total solids were obtained by evaporation to constant weight on a water bath. Usually 2 grams were taken.

Fat.—The fat was determined by the Babcock method. In case the full 17.6 cc. were not available 10 cc. were taken, and the results calculated, to the normal.

Solids not fat.—The solids not fat were obtained by taking the difference between the total solids and the fat.

Proteids.—A slight modification of Ritthausen's method was used in the determination of the proteids. Five cubic centimeters of milk were diluted to 100 cc. and 2 cc. of copper solution (3 gm. copper sulphate to 1 liter) were added. A 6% caustic soda solution was run in until the solution was barely acid to phenol-phthalein. After the precipitate had subsided the solution was filtered through balanced filters, and the precipitate collected and washed on the filter. After drying at 150° C. the filter was extracted with 76° naphtha, and then the naphtha

displaced with ether. The precipitate was dried again at 100° C. and weighed. This last weight minus the weight of the ash of the precipitate gives the proteids.

Ash.—The ash was determined by igniting the total solids until white over a Bunsen burner.

Sugar.—The sugar was determined by difference. In a few samples as a check it was determined directly from the filtrate of the proteids with Fehling's solution.

Errors of analysis.—The different methods of analysis were chosen not so much to get absolute accuracy as to get strictly comparable results. The solids are capable of duplication within .02 %, the fat within .10 %, the proteids .05 %, the ash .01 %, while the sugar when determined by difference would be subject to an error which is the algebraic sum of all the other errors. It is not likely to exceed .10 %. Beside these general errors, individual samples were subject to the doubling of the stated error by the employment of half the usual quantity for analysis, and to accidental errors such as the souring of the sample.

Results of analysis.—A scanning of the indi-

vidual analyses shows a wide variation in each and every constituent, but especially in the fat. The fat varies from .70 % to 7.04 %, and even the samples from the same subject show almost as much variation. Cases A and F, showing a very irregular and a very even milk, illustrate this point. In A the total solids vary much from week to week, but the graphic representation shows at a glance that the variation is due to the fat and not to the other constituents. Such a variation can hardly hold for the average of all the milk supplied at a nursing, and must to a considerable extent be due to differences in the conditions of taking the sample. It is well known in the case of milch cows that the fat increases throughout the milking, and that the strippings are the richest. It is equally true of human milk. The average of Cases A and F further show how little can be deduced from even a series of analyses from one subject. In Case A the fat is almost four times as much, the proteids .3% more, while the sugar is .05% less. These individual differences are only to be eliminated by averaging a large number of samples from many individuals.

Tables showing the averages for each week from the beginning of lactation still show the effect of the individual sample to a marked degree. Here again the variations are mainly in the fat. The solids not fat show a fairly even line. A table

Variation in Composition in Weekly Periods

calculated for periods of four weeks is, however, much more satisfactory. No period is represented by fewer than seven samples, and the number may run as high as nineteen. The straightening of the curve in the graphic table is very marked, and it is hard to escape the conclusion that if the number of samples were large enough the line would still further approach the general average of all the samples. The first two periods must, however, be excepted. In these the proteids are seen to decrease from 1.58 to 1.42 and 1.35.

actation are grouped in Table VII, while the cases of two or more lactations are grouped in Table VIII. The fat in the first lactation averages 1.76%, while it is 3.87%, or more than double, in the other group. From the individual averages it is seen that the highest fat occurs in Case A, the fifteenth lactation; the next highest in Case C, the seventh lactation; while the other two members of this group, E and H, are both higher than the highest of the first group. The proteids do not fall in line so

well, but the highest averages again are in the seventh and fifteenth lactations. The general average of the proteids is .20% more, and of the sugar is .15% less in the second group. These variations are in accord with the variations which occur in the milk of a single individual, that is, a higher fat percentage is usually with a high proteid and a low sugar.

Conclusions.—(1) The average composition of human milk, as shown by 117 analyses, is:

| | | | |
|-----------|------|-----------------|-------|
| Fat, | 2.91 | Ash, | 0.13 |
| Sugar, | 7.01 | Total Solids, | 11.39 |
| Proteids, | 1.34 | Solids not Fat, | 8.48 |

(2) There are wide variations from the average in milk from the same individual at different times.

(3) There are marked variations in the average composition of milk from different individuals.

(4) The average composition of human milk does not vary to any marked extent at different periods of lactation.

(5) During the first lactation the milk, on the average, is weaker in fat and proteids, but stronger in sugar than in subsequent lactations. These differences may or may not be due to age.

Clinical Department.

TRIKRESOL IN PARA-URETHRAL ABSCESS.*

BY M. L. HEIDINGSFELD, P.H.B., M.D., CINCINNATI.

Professor of Dermatology, Laura Memorial College; Clinical Lecturer on Dermatology and Venereal Diseases, Miami Medical College; Dermatologist to Presbyterian Hospital.

ONE of the most troublesome of the long list of vexatious and perplexing diseases which at times impose themselves on the practitioner of medicine is that occasioned from chronic gonorrhea or gleet, which, in spite of the most careful, well-regulated and painstaking treatment, pursues an exceedingly

* Read before the North Kentucky Medical Society, Nov. 13, 1902.

obstinate and refractory course. This unpleasant experience is often shared by genito-urinary specialist and general practitioner alike, and its occurrence is not so uncommon but that any measures which will insure some relief in this direction will be heralded with pleasurable interest.

Many of these cases owe their obstinate character and protracted form to the presence of a complicating prostatitis, vesiculitis or cowperitis, which by reason of their inaccessible character resist successful treatment, and continue to pour their infectious contents into the urethra, and indefinitely prolong the urethritis.

A much larger class, I believe, owe their unduly protracted course to a different and frequently overlooked condition, an extension of the gonorrheal infection into the numerous small glands which extensively line the anterior urethra and glans penis and the external and internal surfaces of the prepuce. Their inflammatory and infectious contents are exuded in the form of a molded filament or shred, and often persists long after an active urethritis has subsided, the urine has become cleared, producing urine loaded with infectious shreds, or dispelling their overburdened contents in the form of a "good morning drop."

Careful palpation will generally reveal their presence in the form of minute indurations, varying from a pinhead to a small shot in size, and the successful management of the case entails their cure, which is often spontaneous, but which can be more promptly insured by careful, systematic dilatation, or passage of sounds.

These so-called para-urethral abscesses often become greatly inflamed and considerably enlarged, varying from a pea to a pigeon's egg in size, rupturing and expelling their highly infectious and purulent contents externally or internally, as the case may be. It is the intention of this paper to deal practically with the management of these forms. Diday,¹ in 1860, first called attention to these forms of peri-urethral abscess, and ascribed to them their gonorrheal origin, and maintained, even at that time, that a gonorrheal urethritis could be indefinitely prolonged by the presence of such an infectious abscess, and that the patient would be subjected to the grave danger of auto-reinfection in case the urethritis at any time yielded to treatment. The microscopic examination of the contents of these abscesses almost invariably reveals the presence of characteristic intra- and extra-cellular gonococci, and Diday's observation has since been amply confirmed by Otis,² Oedmansson,³ Touton,⁴ Pick,⁵ Jaddasohn,⁶ Lang,⁷ Felleki,⁸ Aldor,⁹ Rona¹⁰ and a host of others. Most of the cases post-date the urethral infection, and are the result of the extension of the gonorrheal infection into the ducts of the affected glands. Some not only antedate and secondarily induce a gonorrheal urethritis, but also occur unassociated with an urethritis (Reichmann,¹¹ two cases, Pick,¹² one). It is somewhat difficult to understand how the minute openings of these small glands can become infected and the relatively large patulous urethra escape, unless we accept Finger's¹³ explanation, that the act of micturition carries away the infectious gonococci, or their prolonged undisturbed repose in the recess of some follicle is essential for their full active development.

It is somewhat difficult to estimate the frequency of this form of complication, inasmuch as it is seldom mentioned in genito-urinary statistics, and, when given, mild forms are prone to be overlooked, and very mild ones do not merit special significance. Winternitz,¹⁴ reports three cases out of 359 venereal cases in the University of Prag, for 1892. In my private practice, for 1901, I saw three characteristic and well-defined cases (in two of whom the abscesses were as large or larger than a small marble, while the third was an infection along a duct on the glans penis) out of a total of 102 cases of gonorrheal urethritis. In 1902 I have thus far seen four cases, to about the same proportion of cases. Personal experience therefore leads me to believe that the condition complicates gonorrheal urethritis once in thirty to forty times; but, however infrequent, its presence is always of great significance, and its successful management is of much import to the course of the complicating urethritis. This has been so well impressed upon those who interest themselves in genito-urinary work that every means — free incision and drainage (Aldor¹⁵), extirpation (Pezzoli¹⁶), destruction with electrolysis (Ehrmann¹⁷), or the actual cautery (Touton¹⁸) — has been promptly employed to successfully combat the condition, whenever and wherever it manifests itself. Heretofore, probably the most popular and successful method of treatment, at least of the superficial and favorably situated abscesses, has been destruction with the Paquelin, though incision and drainage has been freely practiced with less reliable results. Extirpation when radically performed promises much to the patient, but because of the more extensive character of the operation and confinement to bed can seldom be readily performed. In my own hands the Paquelin has proven to be the most reliable agent, but its preclusion in the larger and more deeply seated abscesses, together with the unduly prolonged course and thoroughly unreliable results when the other measures were employed, induced me to try, to my knowledge, an entirely new procedure for their successful treatment.

The promptness with which these abscesses refilled when freely incised and drained, and the obstinacy with which they baffled treatment, reminded me of the large indurated obstinate abscesses which often complicated severe cases of postular acne, and induced me to employ a method of treatment which I was successfully using in the treatment of the latter affection: hypodermic injections into the heart of the abscess of minute quantities of trikresol. The marked success which attended the use of this preparation in acne induced me to employ it with equal success in all forms of furuncles and localized abscesses, a single injection often completely aborting them in twenty-four to forty-eight hours. Its use was then extended to large abscesses and carbuncles, with equally gratifying results, and in one instance I believe I aborted an incipient facial erysipelas, by injecting this preparation into its emanating point, a small abscess at the outer angle of the right eye (C. B., Sept. 6th, 1902).

The method of its application is exceedingly simple: An ordinary 15-minim glass syringe, which is provided with a retaining screw, is employed, and, after it is filled with trikresol, is armed with a 26-gauge needle; the air is expressed, and the retaining

screw (Fig. 1, "A") run down, until the fraction of a minim can be carefully measured by proper adjustment of the retaining screw. The proper dose

is then estimated, a drop the size of a bead sufficing for the smallest abscess and a minim or more for the larger ones, and is then injected into the center of the abscess.

Its use, thus far, has been limited to four cases, in all of which it has not only brought to an abrupt close this obstinate form of urethral complication, but has materially shortened the otherwise unduly protracted course of gonorrheal urethritis.

CASE I. H. S., aged twenty-seven years, with a history of several previous gonorrheal infections, covering a period of almost five years, was infected the last time in December, 1900. In June, 1901, several abscesses formed along the anterior border of the urethra, immediately behind the sulcus coronarius. Patient then placed himself under the care of a New York specialist, and a complete extirpation was performed. Patient materially improved, but a mild urethritis persisted, which became quite active after an interval of several months, and was again complicated with abscess formation. On the date of the patient's first visit, Oct. 28, 1901, patient in addition to a very active gonorrheal urethritis, showed two circumscribed abscesses, each about the size of a marble, directly under the line of operative incision. The abscesses were incised and freely drained, patient refusing to again submit himself to a radical extirpation. The gonorrheal urethritis subsided under proper measures, but failed to entirely disappear. In the course of a few weeks the abscesses again reformed, and were excised and drained a second time, on Dec. 22. The improvement was again of only temporary nature, and when the abscesses formed the third time, they were injected with trikresol on Feb. 17, 1902, with the result that by March 31, the date of the patient's last visit, abscesses and urethritis permanently subsided and showed no further active manifestations.

CASE II. J. M., aged nineteen years, was infected with a gonorrheal urethritis for the first time in September, 1901. For an interval of several months patient attempted to cure his own case, by means of patent medicines and borrowed prescriptions, but was eventually obliged to place himself under the care of a physician. Although some improvement resulted from this change, with slight exacerbations and remissions, urination continued painful, and the discharge was abundant and purulent. The patient presented himself for the first time Feb. 25, 1902; there was, in addition to an active purulent, gonococci-bearing urethral discharge, a reddened, inflamed, tender peri-urethral abscess, the size of a large hazel nut, on the under surface of the penis near the scrotum, in the median line. The abscess was incised, drained, and the cavity injected with trikresol, and the urethritis treated with irrigations and injections. Although a fistula formed at the site of the abscess, and persisted for about ten

days, the case improved rapidly, and on date of his last visit, March 26, 1902, patient deemed further attention unnecessary and withdrew from observation and treatment. The patient presented himself several months after the date of his last visit, stating that he had been permanently cured and was free of all manifestations.

CASE III. C. T., aged twenty-seven years, has passed through several gonorrheal infections, and had been entirely free from any active manifestations of the disease for almost two years, prior to the date of his last infection, April 21, 1902. Patient placed himself under my personal care on May 1, and case progressed fairly well, with the exception that a peri-urethral abscess, size of a small hazel nut, formed along the right border of the frenulum, immediate posteriorly to the sulcus coronarius. The abscess was freely incised and drained with iodoform gauze on May 20, and the pus, which was rather abundant, contained characteristic intra- and extracellular gonococci. During the next few weeks the case improved somewhat under persistent treatment, but the abscess soon reformed, and on July 28 its destruction with the Paquelin cautery was attempted. The improvement following this step was likewise only temporary, and when the urinary fistula formed by the radical cauterization closed, the abscess formed for the third time. On Sept. 2 this abscess was injected with trikresol, with the result that by Sept. 23 the abscess had practically disappeared, and the gonorrheal urethritis, which had completely baffled persistent and painstaking treatment from March 1, gradually subsided, so that by Oct. 20, the date of the patient's last visit, all active manifestations disappeared and patient was discharged as well.

CASE IV. D. W. S., aged twenty-one, was infected with gonorrhea for the first time Oct. 2, 1902, and was treated with anterior urethral injections of albargin, 1-1,000, until Oct. 8, when an induration, the size of a large pea, manifested itself on the dorsal surface of the penis, in the sulcus coronarius, and for the time being was diagnosed an initial syphilitic chancre (?), with the question mark affixed. Patient was subjected to permanganate irrigations, every second and third day, but failed to show any material improvement. On Oct. 13, the induration was diagnosed a peri-urethral abscess, and was incised and injected with trikresol. A considerable quantity of gonococci-bearing pus escaped. Irrigations with permanganate were continued Oct. 16, 18, 21, with rapid improvement on the part of the patient, and on Oct. 25, date of patient's last visit, the urine was practically clear and the discharge had ceased.

To recapitulate briefly, the injection of trikresol in all four of these well-defined cases not only effected a complete cure of the abscess, in from seven to fourteen days, but materially cut short what was hitherto, with the exception of Case IV, an exceedingly obstinate, refractory and unduly protracted gonorrheal urethritis. In Cases I and III it effected a prompt and complete cure of the abscess, when radical extirpation, free incision and drainage, and the free use of the actual cautery, measures which find a very esteemed and valuable place in the therapy of some of the most successful and celebrated genito-urinary surgeons, utterly

failed. Although four cases scarcely afford sufficient experience to determine the full efficiency of this preparation in all cases and under all conditions, yet in connection with the marked success which attends its use in analogous conditions, pustular acne and furunculosis, its ease of administration, absence of any marked distress or serious complication, thoroughly suffices, I believe, to warrant its use in every accessible case, until its efficacy, unailing or otherwise, is fully established.

Since the foregoing has been written and presented, I have had the opportunity to try the injections of trikresol in the treatment of an anomalous and I think equally obstinate and distressing form of affection, namely, vulvo-vaginal abscess, and with equally gratifying results. On Nov. 8, 1902, Miss I. S. presented herself with a vulvo-vaginal abscess of the left labium, of the size of a pigeon's egg, tender and sensitive to pressure, and accompanied with considerable redness and swelling of the adjacent area. The abscess was incised, a considerable quantity of pus escaped, whose microscopic examination revealed ill-defined, poorly staining, degenerated pus cells, with an abundance of deeply stained characteristic looking, intra- and extra-cellular gonococci. A few drops of trikresol was then injected into the central portion of the abscess by means of a hypodermic syringe, and an ice bag applied for twenty-four hours. Patient presented herself again on Nov. 11, stating that she had experienced scarcely any pain or discomfort from the operation, and that the swelling and distress she had previously experienced had entirely disappeared. Patient was menstruating at the time, so that a local examination was unfeasible. When patient presented herself on Nov. 15, the labium had assumed a perfectly normal appearance, swelling and inflammation had entirely disappeared, and patient was discharged well.

Medical Progress.

RECENT PROGRESS IN NEUROLOGY.

BY PHILIP COOMBS KNAPP, A.M., M.D., BOSTON

(Concluded from No. 15, page 397.)

* SENSORY DISTURBANCES IN HEMIPLEGIA.

Brécy¹⁴ has found disturbances of sensation in 41 out of 65 cases of hemiplegia, and in 10 out of 12 cases observed from the onset. Disturbances of

localization are the most common. Permanent hemianesthesia is very rare, but defective faculty of localizing sensations of touch or pain is almost constant, and he very often found hypesthesia of the hand and forearm with more or less complete abolition of the sense of position and the stereognostic sense. Analgesia is rare. The disturbances of sensation usually have the same distribution as the disturbances of motion, and are most marked in the extremities. Homonymous lateral hemianopsia is the chief disturbance of special sensibility. The lesion giving rise to disturbances of sensation is either in the posterior portion of the optico-striate region, the Rolandic cortex or the parts between. Lesions in the optico-striate region are more frequent, and of course may involve more of the sensory fibers than a lesion of the cortex. The most intense and persistent sensory disturbances are due to lesions of the thalamus, in front of the pulvinar, in the posterior and inferior part of the external nucleus. Sensory disturbances may also arise from lesions of the posterior segment of the internal capsule.

Gordon,¹⁵ in a study of 35 cases, has also found that ordinary hemiplegia is very often accompanied by disturbances of sensibility. In the upper limb, tactile sensibility was affected in 24 cases, pain in 30, heat in 33, and cold in 28. Sensation is more affected in the upper limb than elsewhere, and usually more affected in the distal portion of the limb. Touch and pain are affected in a slightly smaller number of cases in the leg than in the trunk, but the temperature sense suffers more in the leg than in the trunk. The face is the least affected. The stereognostic sense was affected in 29 cases, but the sense of position was affected in only 17. The faculty of localization of sensation was apparently not examined. The sensory disturbances on the whole ran parallel with the motor disturbances in regard to distribution. From his observations Gordon is inclined to believe that sensory disturbances always accompany motor disturbances of cerebral origin, but that they are often overlooked from lack of sufficient care in the examination.

REMOTE EFFECTS OF INJURIES OF THE CRANIUM.

Viedenz¹⁶ carefully reviews the literature in regard to the influence of injuries of the cranium in producing mental disturbances. In 1,542 insane men observed at Eberswold in fifteen years, he found only sixteen cases in which an injury could probably be regarded as the cause of the mental disease. In a far larger number of cases, however, the injury was the exciting or predisposing cause of the trouble. The injury led to a diminished capacity for resistance in the brain, especially to intolerance of alcohol, and thus to an alcoholic psychosis. The alcoholism may be the result of a moral deterioration, or there may be no actual abuse of alcohol in the ordinary sense, yet the brain is more readily affected by a normal moderate indulgence. From his study of the literature and his own experience he comes to the following conclusions: Injuries of the skull in childhood quite frequently cause imbecility or dementia, which may be complicated with convulsions. In some cases moral degeneracy may develop with good intelligence. An injury of the skull is also capable

¹⁴ Les troubles de la sensibilité dans l'hémiplégie d'origine cérébrale.

¹⁵ *Journ. of Nerv. and Ment. Dis.*, March, 1903.

¹⁶ *Arch. f. Psych. u. Nervenkrankh.*, xxxvi, 363.

of causing mental disturbance in a mentally intact adult, but far more frequently it acts as an exciting cause on an invalid brain or as a predisposing cause on an intact brain for the development of a psychosis. The mental disturbance may come on immediately after an injury, or after a longer or shorter interval. In the interval there are usually some prodromal symptoms. There is no typical traumatic insanity, but all psychoses caused by a cranial injury have certain common features, such as a marked change in character, irritability, failure of memory and intolerance of alcohol. After an injury to the skull we most frequently observe primary dementia, hallucinatory confusion and stuporous states, sometimes with katatonic symptoms, and rarely paranoia. It is doubtful whether genuine epilepsy or genuine general paralysis can develop after an injury, but similar morbid types are often observed. The mental disturbances following an injury to the skull closely resemble those arising on an alcoholic basis. The outbreak of mental disturbances after injury is due less to coarse anatomical changes in the brain than to finer microscopical injuries, which seem chiefly to affect the capillaries. No definite, constant change has yet been found in the ganglion cells. The prognosis in the individual case is to be made in the same way as in similar mental disturbances from other causes.

PARALYSIS AGITANS.

Compin¹⁷ discusses their regular forms of paralysis agitans in which some of the cardinal symptoms may be absent or modified. The tremor may be absent or be hardly perceptible; it may for a long time be limited to one or two limbs, and often be unilateral; it may extend to the tongue, lips, eyelids, eyeballs, vocal chords or the head; and it may be exaggerated by voluntary movements or even be an intention tremor. The muscular rigidity may also be absent or very slight. In other cases it may be so marked as to cause contracture or permanent deformity. There may also be a contracture in extension instead of in flexion. The rigidity may for a long time remain localized in one half of the body, as in hemiplegia. The clinical picture may also be atypical by the exaggeration of certain symptoms, such as retropulsion, pain, etc., or by the addition of unusual symptoms, such as trophic or sensory disturbances, paralysis, cerebral and mental symptoms, or disturbances of secretion. Although the course is usually slow, it may sometimes be very rapid; on the other hand, the disease may remain limited to one limb or one side for many years. Sometimes the symptoms may subside, or, after having been general, may become unilateral again. From this variability in the symptoms, the multiplicity of clinical forms, and the addition of unusual symptoms, Compin is disposed to regard paralysis agitans not as a well-defined morbid entity, but as a symptom complex, produced by a great variety of lesions.

EPILEPSY.

An interesting discussion on the treatment of epilepsy was held¹⁸ at the meeting of the Medical

Society of London, two months ago. Risien Russell, who opened the discussion, stated that the theory of auto-intoxication as the cause of epilepsy had the most supporters, but the question had not been answered in such a way as to put the treatment on a sound etiological or pathological basis. The results of serum therapy and the inoculation of filtered cultures of certain micro-organisms have thus far been unsatisfactory. The bromides are still the most potent agents we have to combat epilepsy, and their supposed ill effects are usually the result of the disease and not of the remedy. He thought the ammonium and sodium bromides had no special advantages over the bromide of potassium, but bromide of camphor deserved further trial. Borax, arsenic, digitalis, belladonna, etc., were sometimes useful adjuvants, but by themselves they had little value. Bromopin was the best of the recent compounds. The exclusion of salt from the diet was of decided importance. Beevor argued against the toxic origin of epilepsy and in favor of the bromides. Ormerod believed borax was sometimes of value, and that belladonna was helpful in *petit mal*. Langdon Down had observed a temporary cessation of the trouble after influenza or pneumonia, but the attacks returned in an aggravated form. Sir Victor Horsley, speaking of the surgical treatment, stated that when general convulsions followed a blow on the head, without obvious evidence of injury, surgical measures were generally of no avail. In the case of definite trauma of the skull, followed by localized convulsions, the question of successful surgical intervention depended largely on the situation of the injury; trephining in the frontal region was unfavorable, and in the occipito-temporal and occipito-parietal regions generally, but not always, without benefit. When the injury was over the motor cortex the skull should be trephined and the cicatricial tissue removed. In cysts and porencephaly in children trephining was often beneficial. In one case, when fits had followed an injury to the spine, the fits ceased after laminectomy; in a similar case laminectomy had no effect. Hystero-epilepsy offered no field for surgical interference.

ISOLATION IN THE TREATMENT OF PSYCHO-NEUROSES.

Dejerine¹⁹ affirms that isolation, as a method of facilitating the employment of psychotherapy, is the sole method which gives favorable results and permanent cures in the treatment of various forms of psycho-neuroses. The ordinary sojourn in a hospital is usually attended with no benefit to a neurasthenic or hysterical patient, and it sometimes is actually harmful. In view of this fact Dejerine has instituted a method of treatment for patients of the hospital class, unable to bear the expense of a private sanitarium, in his wards at the Salpêtrière. The patient, if an adult, is received only on consenting to be isolated. She is put in a bed with the curtains constantly drawn. She sees the physician and his pupils at the morning visit for a few minutes, the interne at the evening visit, and the nurse who brings her meals. No one else can come near her. If badly nourished, as many are, she is given milk hourly, until she takes five or six quarts a day. The psychotherapy begins at the start. She is carefully examined, but never told

¹⁷ Etude clinique des formes anormales de la maladie de Parkinson.

¹⁸ Rev. of Neurol. and Psych., March, 1903.

¹⁹ Rev. Neurol., 15 Dec., 1902.

her symptoms or the diagnosis. Dejerine tells his assistants in her presence that she has no lesion of the nervous system, that the trouble is not serious, and that in time she will be well. Lectures upon a neuropath in the patient's presence have deplorable results. The psychotherapeutic method is simple and is based on reasoning, persuasion and discipline. The patient is informed that the symptoms of which she complains have not the serious significance she fears, and she is not left until conviction begins to dawn upon her. It is necessary to listen to all her ills, but when once her confidence is gained, improvement is rapid. The interne repeats the process in the evening. Isolation is continued until improvement sets in, which generally takes place in ten days or a fortnight. Then isolation is made less stringent; the curtains are opened for an hour or two, permission to receive a letter or a visit is promised if improvement continues and this leads to still greater improvement. Dejerine thinks the results are better among hospital patients than in private practice, because such patients are more docile and submissive to authority, and because the cure is promised publicly, before the corps of assistants. The results obtained by Dejerine in this way are remarkable. Out of 200 cases of psycho-neuroses — hysteria, neurasthenia, mental anorexia, uncontrollable vomiting, etc. — treated by him since 1895, he has met with only two failures.

Reports of Societies.

PHILADELPHIA OBSTETRICAL SOCIETY.

STATED Meeting, March 5, 1903, at 8.15 P.M., the President, DR. J. M. FISHER, in the chair.

DR. L. J. HAMMOND reported

A CASE OF POST-OPERATIVE TETANUS, WITH ESPECIAL REFERENCE TO THE FOCUS OF INFECTION.

The case was that of a female, twenty-two years of age, the daughter of a farmer, whose duties, in addition to household work, included milking cows, feeding pigs and attending to chickens. Previous to her arrival in Philadelphia she had suffered from an attack of (gonorrheal?) peritonitis. Three days after her arrival in the city the patient complained of toothache and swelling in the left cheek, due to eleven carious teeth. This attack terminated in an alveolar abscess, which was incised and cleansed of a considerable quantity of pus. Two days after this had healed, an abdominal section was done for a bilateral pyosalpinx, ovarian abscess on one side and a multiple cystic ovary upon the other. The abscess sacs were removed without rupture. The patient progressed very well until the sixth day, when she complained of strange feelings about the eyes. Four hours subsequently she complained of an intensity of this ocular condition with stiffness of the jaws. Dr. Hammond saw her within an hour after the latter was noted, and found the patient presenting a risus sardonicus. The abdominal incision was examined, and found united without any irritation. Trismus grew rapidly worse, and in five hours after

he saw her, it was impossible to separate the jaws, and at the end of two more hours the muscles of the neck were all completely spastic. No other muscles were spastic until about four hours previous to death (which occurred twenty-seven hours after the first symptoms were noted), when there was noticeable contraction of the muscles of the back and abdomen during the paroxysms only. Morphia, eserine, bromides, chloral and the tetanus antitoxin were all employed. Owing to the tightly closed mouth a culture could not be obtained from the teeth cavities, hence a positive bacteriological proof of tetanus could not be obtained, but the knowledge of the habitat of the tetanus bacillus, and the mode of life of this farmer girl, would tend to convince one that she had become infected with tetanus germ at her home, and that the extensive caries of the teeth should furnish a most vulnerable storehouse for its concealment. As the period of incubation of tetanus is nine to twenty-one days, the germ could not have been introduced at the time of operation.

DR. JOSEPH SAILER: Some years ago during a course in bacteriology at the Pasteur Institute, I was much impressed by a remark made by Roux upon the treatment of tetanus by an antitoxic serum, that there were two classes of cases: the chronic, all of which recovered, and the acute, none of which recovered.

When Dr. Hammond asked me to see this case he had given a million units of the antitoxic serum, and I felt that there was really very little more to be done. My experience is that Roux's remark regarding recovery is pretty nearly true; that is to say, chronic cases recover rapidly under any treatment, and other cases, no matter how early the treatment is instituted or how vigorously carried out, die inevitably. Of course, the most important thing one can do under these circumstances is to arrive at some conclusion in the early stages as to whether there is any likelihood that a case will get well. There is an old rule regarding tetanus: that if the symptoms commence in the upper part of the body, particularly in the head, the prognosis is grave; if they commence in the lower part of the body, the prognosis is very much more favorable. It is easy to theorize why this should be so. If the lesion is in the lower part of the body the toxin reaches the less vital centers of the spinal cord and there is a progressive although very slow immunization of the nervous system so that by the time it reaches the upper portion the nerve cells are able to resist injurious influences. So far as I know there is no evidence that such a theory has any actual basis of truth.

Of course the question of the treatment of tetanus is a most alluring one. The antitoxin is such a trustworthy antidote to the tetanus toxin that Ehrlich and Morgenroth could work out their theories of immunity with mathematical values, which is difficult with antitoxins of many other organisms. It would seem, therefore, that if there is any disease in which antitoxin ought to be efficient it is this one of tetanus. Yet, excepting in the case of some of the smaller animals, whose bodies can be thoroughly saturated with antitoxin, even experimentally it has no curative power, for the reason that the toxins are united with the cells by intermediary bodies and form combinations that cannot be neutralized by the antitoxin, as the toxins in the blood are neutralized by the antitoxin of diphtheria.

In regard to Dr. Hammond's case, when I saw it, the symptoms were most pronounced in the face, and the entire appearance of the patient formed a most typical clinical picture. Even at that time I was compelled much against my will to look upon the prognosis as hopeless, because the patient was beginning to have cramp of the respiratory muscles. The sensation of a binding around the chest is a characteristic symptom, and almost the gravest met with in traumatic tetanus, and indicates that the fatal outcome cannot be long delayed. The tetanus bacillus stays in the original wound without multiplying, and liberates a toxin that travels along the nerve sheaths to the parts of the central nervous system from which the influences which move special muscles arise. As the peripheral neurons are the parts first affected, they appear to be also the parts in which the symptoms are first manifested. The fact that this patient's symptoms began in the eye and extended to the face led me to suspect some other focus of infection than the abdominal wound, and it seems probable that there was infection in the jaw. Cultures would not have been of much value. A few investigators have been able to obtain the tetanus bacillus from the original wound. In one case the bacillus was said to have been obtained from the neighboring lymph glands. But the majority of observers, no matter how carefully investigations were undertaken, have been unable to find it, and for pretty obvious reasons. It does not multiply. It appears in small numbers, and usually is a rather difficult germ to grow.

It is hardly worth while to mention that there is probably no germ more difficult to destroy than the tetanus bacillus. It is more difficult than the anthrax, because it is anaërobic, and it fails to grow in the intervals of fractional sterilization, unless put under anaërobic conditions. The spores can be boiled for twenty-four hours without being destroyed. A few instances of aerobic tetanus bacilli have been described. I think if methods could be adopted by which the tetanus bacilli could be killed all further measures would be unnecessary, because no other organism can resist the condition required to destroy it. I have been interested in the gelatine treatment of hemorrhage. In going over the literature it is surprising to find how frequently patients injected with gelatine for checking hemorrhages have died of tetanus. Some five or six cases are now on record. The reason is that the tetanus bacillus in gelatine media cannot always be got rid of by boiling at intervals. I can only agree with Dr. Hammond in his idea of the case, that it was an infection probably carried with the patient from her home and lodged in the tooth. I should be rather inclined to differ with him in his view that the depressed state of the patient had promoted the infection. I should rather think that perhaps the latent focus had been aroused by the suppuration in the jaw, or even by the operation upon it.

DR. F. C. HAMMOND: Coe of New York in 1901 reported two cases of tetanus following aseptic celiotomy. One case was similar to the case reported by Dr. Hammond as regards the pelvic condition, bilateral pyosalpinx (gonorrheal). In this case tetanus developed during the latter part of the third week. The patient had progressed so well from the opera-

tion that she was permitted to lie upon a couch on the sixteenth day. On the twenty-fourth day, while around the ward, her legs "gave way," precipitating her to the floor. For a few days previous there had been some difficulty in swallowing, and stiffness of the muscles of the neck. Owing to her known hysterical nature, these were considered of an hysterical character. Subsequently sufficient symptoms developed to warrant a diagnosis of tetanus. The patient died on the thirty-sixth day after the operation and the twentieth after the appearance of the initial symptoms. In the second case stiffness of the muscles appeared on the ninth day, and the patient felt inclined to be hysterical. A diagnosis of hysteria was made. On the next day marked tetanic symptoms appeared, and the patient succumbed on the eleventh day after the operation. In both cases an early diagnosis of hysteria was made, which was verified by a consultant. The diagnosis of tetanus was not made in either case until trismus had developed. It hardly seems possible in the modern day of aseptic and antiseptic surgery that we should look for tetanus as a complication of abdominal section.

DR. H. D. BEYEA: I would like to ask Dr. Hammond to what extent and how the water used in this operation was sterilized. In a plastic operation, cervix and perineum, performed by Dr. Penrose in a private house a few years ago, tetanus developed and resulted in death. The nurse in attendance, not accustomed to prepare for such an operation, it was found had not properly prepared the water. It had been taken from a well after a storm, and was muddy. This was observed when it was too late to resterilize the water, and therefore mercuric chloride was added. There seemed to be no question of doubt but that the water was the source of the infection in this case. Shortly afterward there occurred at the University Maternity two or three cases of tetanus with the same result. It was discovered that the water used for douching was taken from the tap and prepared by adding mercuric chloride. The infection here was positively traced to the water. It would seem to me, since the tetanus bacillus is so frequently found in water, that unless the water is sterilized by fractional sterilization, boiled for at least two hours on two consecutive days, or sterilized in the Sprague-Schuyler sterilizer under fifteen pounds pressure, we should look to the water as the probable source of infection. Aside from catgut, it is practically the only source of infection in abdominal technique.

DR. B. C. HIRST: The cases that occurred in the University Maternity were three in number, and all due to the water of intrauterine douches, I am sure. We had at that time a resident physician who conceived the idea that every woman's womb must be washed out after labor. Every unfortunate woman had an intrauterine douche, whether there were any complications or not, and three died of tetanus. We had the water examined after the first case, and in the sediment collected from the tap water there were demonstrated the bacilli of malignant edema and of tetanus. Animals injected with the bacilli died, some of malignant edema and some of tetanus. We had boiled the water, but we immediately installed a Sprague-Schuyler sterilizer, the first, I believe, in the University Hospital.

It is a curious fact that the mistake should be made so often of mistaking tetanus for hysteria. I have seen three cases in which this mistake was made at different times, in different localities, and each by a different consultant.

DR. HAMMOND, in closing, said: I thank the gentlemen very much for the discussion, which has amounted to so much more than the paper that I have learned a great deal from what I felt to be a very uninteresting subject.

I took advantage of the suggestion made by Dr. Sailer as to the prevention of any subsequent cases of tetanus by first cleansing the entire institution with 1-500 bichloride solution, and liberated two tanks of oxygen in each room with the hope that pure air might contribute something toward preventing such condition. I never before had a case of tetanus, and have not since. In the same week there were four major operations in the same institution, and the water that was used was first filtered and then boiled eighteen minutes. So it seems to me improbable that the infection was in the water. If so, we would have heard something more of it in the other cases, all of which were prepared in precisely the same way both as regards the water and instruments. The case directed itself so clearly toward the teeth as the focus that I have learned the lesson that whenever I have a patient from the country districts the first thing I expect to do, and for which I shall accuse myself of negligence if I do not do, is to inspect the teeth, having any carious teeth looked after before operation. In answer to Dr. Beyea's question, I can but repeat that it seems highly improbable that the germ was in the water. I do not think in this case there was any possibility of mistaking the diagnosis for that of hysteria. Hysteria never entered my mind. The lectures I heard when a student so impressed me, especially in regard to the peculiar expression [risus sardonius], that from the appearance of this in my patient, I felt no doubt as to diagnosis.

DR. M. H. BOCHROCH read a paper on

BIRTH PALSIES.

The obstetrician, he said, does not always take into consideration the accidents to the child which so frequently eventuate in serious and permanent palsies. These injuries are not always evident at birth; very frequently they do not receive attention until years after, and then at the hands of a neurologist, whose function is usually limited to making the diagnosis of a permanent and hopeless lesion. Birth palsies occur more frequently in the practice of the general practitioner than in the hospitals and wards attended by professional obstetricians. In brain lesions, such as hemiplegias, microcephaly, porencephaly and hydrocephalus, forceps are as a rule used too late rather than too soon; that prolonged pressure, such as occurs in primiparae, is more often the cause of this deplorable state than the improper use of the forceps. In cases of cerebral hemiplegia or cerebral diplegia, the most that can be accomplished is a tedious and only partially successful attempt at education, and some training of the paralyzed limbs. It would seem that in every child in whom at birth there are present symptoms of asphyxiation following dystochia, and in whom there has been prolonged pressure and constriction

of the head, it would be a justifiable procedure to rapidly make an opening of moderate size upon either side of the parietal region; by such a procedure the effused blood escapes, or could be washed out with a normal salt solution. Erb's palsy is detailed, stress being laid upon the avoidance of the various procedures which predispose to this condition. The treatment of brachial palsy resolves itself into the employment of massage and electricity. The paralyzed arm should not be allowed to hang helplessly by the side, but should be supported in a sling or in a Velpeau bandage. In some of these cases nerve suturing may be indicated.

DR. GEORGE M. BOYD: I have been fortunate enough not to meet with any of the palsies seen as the result of difficult forceps operation. I have never met with a case of brachial palsy. The doctor speaks of prolonged labor superinducing the palsies rather than the labor assisted by forceps interference. It seems to me that very many of the injuries that we meet with, and possibly the great number of asphyxias and fetal deaths, are due to too early interference, injudicious or faulty use of the forceps.

DR. STRICKER COLES: I have been so unfortunate as to have one case of palsy of the arm in difficult labor. The shoulders were very difficult to deliver, and twenty minutes were used in making traction. I thought at one time I would not be able to deliver them at all. It was a typical case of palsy as described by Dr. Bochroch. I heard occasionally from the child, and at one time that she was at the Polyclinic Hospital, where it was thought to make an x-ray picture, thinking the palsy was due to displacement. This was refused, and the last I heard of the patient was that she had diphtheria and died.

The only other form I have known of is facial paralysis, occipito-posterior delivery with forceps. The paralysis disappeared in five or six days, and I have seen no bad results following the paralysis.

DR. L. J. HAMMOND: I have been very much interested in the surgical treatment of peripheral nerve injuries, and my feeling is that in this unfortunate condition we have a lesion justifying surgical treatment. As Dr. Bochroch has said, we have the condition due either to extravasation of blood from rupture of the venous plexus, which surrounds the cord (extra-durally), or we have inflammatory lymph deposited within the sheath itself. If this be correct it seems to me that we have in operation a relief that should be undertaken in cases that do not respond to the routine medical treatment within a reasonable period. If operation is delayed until nutritive changes take place, it is probable that nothing can be done. I should like to hear from Dr. Bochroch regarding results of treatment.

DR. W. S. STEWART: I should like to call the attention of the society to another form of palsy which we might find on investigation. I presume that most of the members of this society do not believe in maternal impressions. I have had in my experience a case resembling that described by the reader of the paper, but which I could trace back to maternal impressions. The child's left arm was paralyzed and hung at its side. The mother was disposed to accuse me of injuring it in her delivery. Prof. D. Hayes Agnew was consulted, and said

that there was nothing to indicate that the child had been injured in delivery. I inquired of the mother whether she had been disturbed in any manner by seeing a person with a similar condition. She at first said, No. Then she replied, except that a man had sat opposite her at her table who had no use of one arm. I told her I believed that to be the cause of the child's condition, and that it would be well to try electricity. I did not believe the condition would ever improve. That child, unfortunately, did not die as in the case mentioned, and is living today with the same condition, unhelped by various treatments and numerous doctors. I had another case which occurred with a woman sitting opposite a man at her meals, with a glass eye. When her child was born it had a corresponding sightless eye. In another case a pregnant mother gave birth to a child that had constant movement similar to chorea, and I learned that the mother while carrying the child was riding in a street car with a woman whose child was choreic. I could give you many other cases without doubt results of maternal impressions. While this society may not feel much interest in this subject, I think it is often well to trace such occurrences to the true source.

DR. E. P. BERNARDY: There is no doubt that a prolonged labor can cause serious brain lesion to the newborn child, the excessive overlapping of the parietal bones causing rupture of the blood vessels and injuring the delicate coverings of the brain, but the true cause of many brain lesions, especially those of late appearance, are caused mostly by the injuries occasioned by misapplied forceps. While the forceps are valuable both to mother and child, it is a well-known fact that they may become the reverse.

In an experience of nearly five thousand confinements, I can hardly recall a case injured by a prolonged labor, where forceps were not applied. In my earlier obstetrical practice the application of forceps was one in about five cases, while at the present it is one in about fifty or a hundred confinements.

In an article which I published upon the "Use and Abuse of the Obstetrical Forceps," the statistics showed that in America the forceps was applied in every fifteen confinements. Therefore, I cannot believe that these injuries are produced from lack of the use of the forceps.

DR. F. C. HAMMOND: Regarding Duchenne's paralysis, the experiments of Stolper conclusively prove that the plexus cannot be compressed by the tips of the forceps so long as the child presents by the vertex, although it may occur in face and brow presentations. Dr. F. X. Dercum states that he has never seen a case of palsy, cerebral in origin, occur in a multipara. From the standpoint of prophylaxis it would be well to apply forceps just as soon as the fetal head fails to recede between the pains.

DR. BOCHROCH: Regarding Dr. F. C. Hammond's remarks I cannot go into details concerning in what particular presentation the forceps do the most damage. It is well to remember Erb's point high up on the neck the site of the origin of brachial palsy, and that if the forceps lie over too far palsies may be made in that way. In some articles it is shown that the sole cause of palsies is that the forceps are put on in a bungling fashion, pressing on Erb's point. It is a very curious fact that facial palsies usually disappear in two or three days. I

mentioned in my paper that nerve suturing might be resorted to. I am not, however, familiar with a case in which it has been done. Nerve suturing is receiving considerable attention from the surgeons, and they will have to decide that question.

I think Dr. Bernardy did not understand me; I tried to make clear that it was the want of proper use of the forceps, rather than the early use, which caused injuries. The fact that the forceps are not used early enough, and prolonged pressure permitted, especially in primiparæ, is, I think, the frequent cause of the palsies encountered.

Recent Literature.

Medical Microscopy. Designed for Students in Laboratory Work and for Practitioners. By T. E. OERTEL, M.D., Professor of Histology, Pathology, Bacteriology, University of Georgia. With 131 illustrations, some of which are colored. Philadelphia: P. Blakiston's Son and Co. 1902.

The author has attempted to present in a small volume of 350 pages the essentials of clinical microscopy, and has succeeded admirably. The book is suited especially for practitioners, who, unable to take a post-graduate course, wish to acquire sufficient knowledge and skill to avail themselves of the aid the microscope offers for diagnosis. The writer has wisely restricted himself to those methods which have proved the best for routine work. Dr. Oertel evidently possesses a thorough first-hand knowledge of the subject and a familiarity with the recent literature.

We think it would have been better to have omitted the chapter on tumors. The diagnosis of tumors is too difficult and involves too great a responsibility to be undertaken by any one who has not had prolonged and thorough instruction under some competent teacher.

The book is printed on heavy opaque paper, from large clear type.

Lessons and Laboratory Exercises in Bacteriology.

An Outline of Technical Methods Introductory to the Systematic Study and Identification of Bacteria. By ALLEN J. SMITH, M.D., Professor of Pathology in the University of Texas. Philadelphia: P. Blakiston's Son & Co. 1902.

This work consists of eighty-three exercises in general bacteriological technique and explanatory notes. A description of the characteristics of the important pathogenic bacteria is not included. The author has employed a new terminology. The old familiar names of nearly all the pathogenic bacteria have been discarded, and are not mentioned even as synonyms; for example, there is no reference to *Staphylococcus pyogenes aureus* in the index; *Bacillus pyocyaneus* is designated *Pseudomonas pyocyanea*, a term which has been abandoned by Migula, who introduced it.

Antiquated methods and complicated procedures unsuited for elementary students are given, while some of the simple and valuable recent methods are not mentioned. There are not a few errors in the text. The book is printed on poor paper and the illustrations are crude.

THE BOSTON
Medical and Surgical Journal

THURSDAY, APRIL 16, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.
SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.
All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.
All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.
Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (INCORPORATED),
283 WASHINGTON STREET, BOSTON, MASS.

THE RELATIVE MEDICAL AND SURGICAL FERTILITY OF THE DIFFERENT NATIONS DURING THE PAST YEAR.

THE following statistics are by no means a guide to all the articles published during the past year, but are made up from the articles considered worth epitomizing by the editors of Gould's Year Book of Medicine and Surgery for 1903. As these abstracts are as nearly as possible a report of all that is new in medicine and surgery for this period, they are perhaps as good a guide as may be found in regard to what country is at present the most active in furthering medical advance. It is not supposed that the statistics are accurate; in the first place they are from the American point of view; secondly, occasional individuals of one country publish their work in periodicals of another country; thirdly, much of the best work that is being done is not reported within the year, and, fourthly, the importance of certain pieces of work cannot be inferred from these figures (for instance, Ehrlich's immunity counts the same as some minor report of a new operation or a new instrument); but admitting the evident errors, the statistics may not be without interest as showing the tendency of the times.

NUMBER OF ARTICLES EPITOMIZED IN GOULD'S YEAR BOOK FOR 1903.

| From. | Medical. | Surgical. | Total. |
|-------------------------------|----------|-----------|--------|
| United States | 704 | 629 | 1,333 |
| German Empire and Austria . . | 873 | 217 | 1,090 |
| Great Britain and Ireland . . | 313 | 246 | 559 |
| France | 312 | 131 | 443 |
| Italy | 102 | 11 | 116 |
| Russia | 22 | 2 | 24 |
| Canada | 13 | 12 | 25 |
| Australia | 4 | 10 | 14 |
| Hungary | 4 | 2 | 6 |
| Norway and Sweden | 5 | 0 | 5 |
| Holland | 8 | 6 | 11 |
| Switzerland | 2 | 0 | 2 |

| | | | |
|-----------------------|-------|-------|-------|
| India | 2 | 1 | 3 |
| Finland | 1 | 0 | 1 |
| New Zealand | 1 | 0 | 1 |
| Mexico | 1 | 0 | 1 |
| Uruguay | 1 | 1 | 2 |
| | 2,368 | 1,271 | 3,639 |

From this it may be seen that last year the United States published the largest number of articles containing something new; that in surgery the United States has published almost as many articles as all the other countries together (629 to 642); that in medicine Germany and Austria have produced the greatest number of medical articles; yet America's lead in surgery is greater than Germany's lead in medicine. Also, that while most countries tend to an excess of medical reports over surgical (namely, Germany, France, Italy, Russia, Norway and Sweden), the English-speaking countries tend to produce a more equal proportion of the two subjects (namely, United States, Great Britain, Canada and Australia).

NUMBER OF ARTICLES PRODUCED IN SPECIAL SUBJECTS.

General Medicine.

| | United States. | Great Britain and Ireland. | German Empire and Austria. | France. | Italy. |
|--|----------------|----------------------------|----------------------------|---------|--------|
| Infectious diseases | 42 | 24 | 40 | 18 | 6 |

| Appendix | 26 | 3 | 3 | 0 | 0 |
| Hernia | 10 | 5 | 3 | 2 | 0 |
| Liver, gall bladder and spleen. | 28 | 6 | 3 | 4 | 0 |
| Respiratory organs | 9 | 1 | 3 | 1 | 0 |
| Vascular system | 11 | 6 | 1 | 4 | 0 |
| Diseases and fractures of | | | | | |
| bones | 6 | 8 | 1 | 1 | 0 |
| Joints and dislocations . . . | 1 | 7 | 1 | 0 | 0 |
| Venereal diseases | 15 | 2 | 4 | 2 | 0 |
| Brain and nervous system . . | 21 | 7 | 1 | 4 | 0 |
| Muscles and fascia | 1 | 3 | 0 | 0 | 0 |
| Spine | 9 | 3 | 1 | 0 | 0 |
| Kidneys and ureters | 27 | 10 | 1 | 2 | 0 |
| Genitals (male) | 34 | 13 | 5 | 5 | 0 |
| Plastic surgery | 13 | 14 | 1 | 0 | 0 |
| X-rays | 14 | 2 | 0 | 0 | 0 |
| Obstetrics | 42 | 27 | 36 | 15 | 4 |
| Gynecology | 17 | 17 | 69 | 21 | 2 |
| Orthopedics | 10 | 3 | 3 | 0 | 0 |
| Ophthalmology | 102 | 10 | 28 | 26 | 5 |
| Nose and throat | 53 | 9 | 10 | 15 | 2 |
| Otology | 21 | 6 | 8 | 9 | 0 |
| Anatomy | 6 | 15 | 52 | 3 | 1 |

From the first list (medicine) it may be seen that Germany's forte lies especially in tuberculosis, diabetes, gout, rheumatoid arthritis, blood, digestive, urinary and renal diseases, physiology and physiological chemistry; that America's forte lies in pathology and bacteriology, nervous and mental diseases, cutaneous diseases and legal medicine; that France's forte lies in nervous and mental diseases and syphilis. It is interesting to note that the two nations best known to be of a nervous temperament should excel in articles concerning nervous and mental diseases. From the second list (surgery) the United States seems to be strongest in technique, anesthetics, surgery of the peritoneum and intestines, appendicitis, surgery of the liver, spleen, genito-urinary tract and spine, x-rays, orthopedics, ophthalmology, nose and throat, and otology. The British Isles are strongest in cysts, tumors, diseases of the joints, dislocations and plastic surgery; while Germany is strongest in gynecology and anatomy.

For a true criterion of the fertility of the different races of physicians, however, percentage ratios must be considered:

| | France. | German Empire and Austria. | Great Britain and Ireland. | United States America. | Italy. |
|--|---------|----------------------------|----------------------------|------------------------|--------|
| Ratio of physicians to 10,000 inhabitants. | 3.9 | 4.6 | 6.1 | 16.1 | 6.3 |
| Actual number of physicians | 14,445 | 40,552 | 26,831 | 123,251 | 20,437 |

| | | | | | |
|--|-------|-------|-------|-------|-------|
| Per cent of all medical articles pub'd. | 13.17 | 36.86 | 13.21 | 29.72 | 4.30 |
| Per cent of all surgical articles pub'd. | 10.31 | 17.07 | 19.36 | 49.40 | 1.10 |
| Per cent of total articles published. | 12.17 | 29.97 | 15.37 | 36.66 | 3.19 |
| One article to how many physicians? | 32.63 | 37.0 | 47.6 | 92.4 | 176.0 |

In other words, the French produced during the past year one article to every 32.6 physicians; the Germans, one to 37; the English, one to 47.6; the Americans, one to 92.4, and the Italians, one to 176.

Apparently, then, the French are the most productive, whereas the position of the Americans is well toward the bottom of the list.

THE SPRING MEDICINE IDEA.

Our correspondent, in another column, suggests a query which has no doubt occurred to many others, as to the significance, if there be any, of the deeply rooted idea that spring brings with it certain peculiar physical dangers and medical responsibilities. Whatever its source may be, the supposed necessity of a "spring medicine" has invaded the minds of regular practitioners of medicine to an extent which at least excites our curiosity, and stimulates enquiry.

The successful quack is, after all, usually a person of keen perceptions, who finds it useful to study human peculiarities and prey upon human weaknesses in a way which appears illegitimate to the more reputable practitioner. Man hibernates less conspicuously, no doubt, than some of his lower congeners, but, nevertheless, his attitude toward life varies more than he suspects during the winter as contrasted with the summer months. If he is unwise, as most men are, he wears thick underclothing in winter, he refrains from physical exercise, certainly in the open air, his uric acid tendencies assert themselves, he labors with his mind, regardless of his body, and spring finds him ready for the rejuvenating medicine, which he finds advertised in every newspaper and in every street car. Proverbially of weak reasoning capacity in matters medical, he attributes his steady improvement in physical condition to sarsaparilla or hypophosphites, or other more mysterious draughts, instead of to the natural accompaniments of the salubrious weather of spring, golf, the trout brook, uncontaminated air and the completer excretion of waste products.

In the meantime, with this somewhat insecure basis of physiological fact, the quack, whether without or within the fold, finds his opportunity, and spring is turned into a veritable plague spot in the calendar. Our sins of the winter are visited upon

us many fold magnified, and we enter upon the summer journey with trembling steps, leaning upon the staff of the saving "spring medicine." With this aid we revive, and the "spring medicine" has vindicated itself beyond the power of argument to refute.

Such is, undoubtedly, the popular attitude toward this season of the year, brought about by a small amount of fact, unscrupulous quackery, skilful advertising and a willingness to be duped, which is apparently instinctive in the human animal. This is, in fact, but one of many curious superstitions regarding health which are transmitted from generation to generation, and unquestioningly accepted by the world at large. A good share of the enlightened physicians' work should be to combat these tendencies of which medicine, even today, is full; but the slightest experience shows how difficult a matter this is, and what is more regrettable, how often the doctors themselves condone and encourage them. We are inclined to think that the spring medicine idea simply represents a flagrant example of an exceedingly common tendency. We are still far too inclined to allow our patients to think that they are "nervously exhausted," instead of being simply undisciplined, or that they have been "threatened" with pneumonia, or "caught" a cold, or narrowly escaped some other physical calamity. This attitude is certainly akin to the spring medicine idea, which we openly deplore. The moral is sufficiently plain.

THE REVIVED INDEX MEDICUS.

WE are in receipt of the somewhat delayed first instalment of the *Index Medicus*, bearing the date January, 1903. The general appearance of the publication is very similar to that with which we are familiar in the numbers previously published. A somewhat larger type has, however, been used, which is certainly to be regarded as an improvement. This new series of the *Index Medicus* begins, as already announced, with the year 1903, but a certain number of foreign journals for December, 1902, have been included in the titles given. It is announced that numbers two and three, for February and March, will be issued as a double number, since the material has sufficiently accumulated owing to the enforced delay in the publication of the first number. In a notice printed at the head of the current number it is stated that the classification adopted is based as far as possible upon the latest accepted views in medicine, but it is to be remembered that the bibliographer has to deal with a large amount of material which cannot be systematically classified.

This work, which has been again undertaken under the auspices of the Carnegie Institution at Washington, must appeal to every physician and scientific man who looks into the literature beyond his weekly journal. Its discontinuance several years ago was universally deplored, but at that time resources were not available for its continuance. There can be small doubt that, under the present auspices, such a lapse can hardly occur again, certainly not in the immediate future; nevertheless the profession at large should feel a sense of responsibility in liberally supporting the publication through subscription. It is evident that the work of the editors must enlarge year by year with expanding knowledge, and that, therefore, the expense of continuing the *Index* will constantly increase, an added reason for the generous support of the medical profession at large.

MEDICAL NOTES.

NEW JERSEY STATE BOARD OF MEDICAL EXAMINERS.—The State Board of Medical Examiners of New Jersey has secured amendments to the Medical Practice Act of that State, by which the academic standards for admission to the State examinations have been raised from a competent common school education to a diploma issued after four years of study in a normal, manual training or high school of the first grade in that State, or its equivalent. The medical requirements have been increased from three to four courses of medical lectures of at least seven months each, in different calendar years, prior to receiving the degree of Doctor of Medicine. The amendments go into effect July 4 next. After that date, candidates for examination or for the endorsement of a license issued by a recognized examining board of another State will be obliged to comply with the new standard of requirements for a New Jersey license.

INCREASE IN THE MEDICAL CORPS OF THE NAVY.—The Fifty-seventh Congress in its last session provided for an increase of one hundred and fifty members in the Medical Corps of the Navy, twenty-five of which are to be appointed each calendar year for six years. By the enactment of this law there is afforded to the young physicians of the country an opportunity to take service in the Navy of the United States and an assurance of the continuance of this opportunity for the next six years. The number of vacancies in this Corps occurring from retirements, resignations and casualties average about ten a year, which, added to the twenty-five created by new legislation, makes thirty-five appointments open to ambitious young medical men yearly.

These appointments are to be made in the grade of assistant surgeon, and are within the reach of any well-qualified physician between the ages of twenty-one and thirty who is a citizen of the United States. Examinations to determine the fitness of candidates for appointment are held in Washington, D. C., and at Mare Island, Cal., and the boards of examiners are in continuous session throughout the year. It is only necessary for any physician of the required age and citizenship desiring to enter the Medical Corps of the Navy to apply to the Secretary of the Navy for permission to be examined to insure being given an opportunity. No political or other influence is required, and the only testimonials needed are those bearing on moral standing and citizenship. The examinations to determine the fitness of candidates for these appointments are conducted in the following order: (1) physical; (2) professional; (3) collateral. Further particulars can be had by addressing Bureau of Medicine and Surgery, Navy Department, Washington, and referring to No. 78,399.

THE WIDAL REACTION IN MALIGNANT ENDOCARDITIS. — W. Hale White, M.D., and W. C. C. Pakes report the case of a young woman dying of typical malignant endocarditis, upon whom during life a characteristic Widal reaction was obtained. Examination showed that the patient had not contracted typhoid fever after the onset of the endocarditis, and the case is, therefore, of interest that in endocarditis of streptococcus origin there was developed in the blood serum substances capable of agglutinating in the strength of 1 to 20 *B. typhi abdominalis*. In the experience of these writers the Widal reaction has not hitherto been obtained in endocarditis.

TRANSMISSION OF MOSQUITOES BY VESSELS. — According to the bulletin of the Yellow Fever Institute, from investigations which have been made regarding the transmission of mosquitoes by vessels, the general conclusions are drawn: first, that mosquitoes may come aboard vessels under favorable conditions when the vessel is not over fifteen miles from shore; second, that *Stegomyia* may be carried from Mexican or West Indian ports to those of our Gulf States; third, that they may board a vessel lying at anchor a half mile or less from shore, being conveyed by the open lighters used or flying aboard, and, finally, that a vessel moored a short distance from land may become infected with yellow fever.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, April 15, 1903, there were reported to the Board of Health of Boston

the following cases of acute infectious diseases: Diphtheria 31, scarlatina 25, typhoid fever 11, measles 30, smallpox 0.

A MEMORIAL TO DR. HORACE WELLS AS DISCOVERER OF ETHER. — A memorial service to Dr. Horace Wells as the discoverer of ether was held at the Center Church at Hartford, Conn., last Sunday. A memorial window to him and to his wife was placed, and the medical and dental societies of Hartford attended the ceremony. There is a statue to Dr. Wells in Bushnell Park, Hartford.

NEW YORK.

HOSPITAL SATURDAY AND SUNDAY ASSOCIATION. — The Distributing Committee of the Hospital Saturday and Sunday Association met in the Mayor's office on April 7, to give out the money contributed at the annual collection to the institutions represented in the association. There are thirty-seven of these, and the amount apportioned to each is on the basis of the amount of free work done during the previous year. The general agent of the association reported that the total collection was a little over \$82,000, of which \$9,902.75 was designated for particular hospitals. Deducting from the balance \$4,638 for expenses, there remained for distribution on the basis named the sum of \$68,000. The five hospitals receiving the largest amounts were the following: The Montefiore Home and Hospital for Chronic Invalids, \$6,800; Mount Sinai Hospital, \$5,245; St. Luke's Hospital, \$4,323; Roosevelt Hospital, \$4,233; and the German Hospital and Dispensary, \$4,009.

COLUMBIA UNIVERSITY, MEDICAL DEPARTMENT. — At the monthly meeting of the trustees of Columbia University, held April 6, the following changes were announced in the College of Physicians and Surgeons: Dr. George M. Tuttle has resigned from the professorship of gynecology; Dr. Arnold H. Knapp has been appointed lecturer in ophthalmology; Dr. John S. Thatcher, clinical lecturer in medicine, and Dr. E. L. Dow, demonstrator of pathology. The gift was received from the daughters of the late Dr. Minturn Post, who was graduated from Columbia in 1827, of the valuable collection of minerals made by Dr. Post.

DISEASED CATTLE FOR SLAUGHTER. — A deliberate attempt to send a carload of diseased cattle for slaughter in New York was recently foiled by the State Agricultural Department. Word was received of the shipping of the stock from Newport, Herkimer County, and the car was intercepted in the railroad yards in New York by the department's agents. Of twenty cows found in the car, three were in a dying condition, and soon expired. Eight

others were suffering from advanced tuberculosis, and at least three from pneumonia. It was also learned that several others of the herd had died at Utica, before they could be transferred to the car on the New York train. It is intended to prosecute the shipper of the cattle.

A CENTENARIAN.—Daniel Butler, the oldest resident of Tompkin's County, died at Enfield Falls, near Ithaca, on April 7, at the age of 104 years.

THE TYPHOID EPIDEMIC AT ITHACA.—An official statement in regard to the typhoid epidemic at Ithaca, dated March 29, has been given out by Dr. Soper, the representative there of the State Board of Health, in reply to a letter from the New York State Teachers' Association, inquiring whether it would be safe to hold a meeting of that society scheduled to take place at Ithaca the first week in July. In it Dr. Soper states that a careful consideration of the matter leads him to express the opinion that the meeting could be safely held there. In the last four weeks, he says, marked improvements are observed in the typhoid situation, and the course of the epidemic seems to have been run. Beginning early in January, the epidemic increased rapidly, until on Feb. 2 there were thirty-eight cases in a single day. From that date it diminished slowly until the 22d, when its decline became more rapid. He gives the total number of cases as 681, and the deaths at 51, but states that these figures are probably not accurate, the statistics of the epidemic being not yet compiled. There have been 54 new cases in March, of which 36 were reported in the first two weeks and 18 in the last fortnight. In his view, the security of health in the near future depends partly on a sanitary organization formed within the last month and partly on the probability that the original source of infection no longer exists. If the measures which the authorities are capable of carrying out are executed, there should be but little more danger of typhoid fever in Ithaca during the coming spring and summer than in any other city of similar size and location. Indeed, he thinks, there is probably no other city in the country in which the health of the people could be so vigilantly guarded. After describing the sanitary measures which are being carried out, he says: "The health of the community, as indicated by the prompt and accurate returns now being made by physicians, is such as to warrant the confidence that typhoid fever in the epidemic form is passed. It is to be expected that a few more cases will occur, as it would be unreasonable to suppose that the last spark of the conflagration has been extinguished. If the food, milk and water supply are kept free from infection from the surrounding

country, and infectious matter in the town is destroyed, there will be no opportunity for another outbreak." As a matter of fact, a few cases have occurred during the last week.

Miscellany.

A SERIES OF FACSIMILE REPRINTS OF MEDICAL AMERICANA.

Few copies of the early contributions to medical literature written by Americans and published in this country are in existence. From an historical standpoint these early American contributions to medical science are worthy of better fate than that which has attended them until finally and safely lodged in a corporate library. For the better and more permanent preservation of these valuable monographs, the *Medical Library and Historical Journal* has undertaken the reproduction of a series of these in facsimile.

The first to be published will be "The Abuses and Scandals of Some Late Pamphlets in Favour of Inoculation of the Small Pox, Modestly obviated, and Inoculation further consider'd in a Letter to A—— S——, M.D. & F.R.S., In London," a monograph by William Douglass printed by Franklin at Boston in 1722. Photographic plates of the book will be made in exact facsimile, and an illustrated prefatory sketch (historical, biographical and bibliographical) will be written by Lewis Stephen Pilcher, A.M., M.D., LL.D., the widely known medical *bibliophile* and editor of the *Annals of Surgery*. The issue will be strictly an edition de luxe, limited to 150 signed and numbered copies, printed in the best style of the typographical art, on large paper and bound in gray boards.

Numbers will be assigned in the order in which subscriptions are received. The price of each book will be \$1.00 net, payable on delivery. After the limited edition has been printed, the plates will be destroyed and the book will not be re-issued.—*Medical Library and Historical Journal*.

Correspondence.

THE PREPARATION AND DISTRIBUTION OF ANTITOXIN BY THE MASSACHUSETTS BOARD OF HEALTH.

Boston, April 13, 1903.

MR. EDITOR :—So long as the statements of Mr. W. W. Bartlett before the Committee on Public Health of the Massachusetts Legislature concerning the antitoxin work of the State Board of Health were directed only to the committee, it did not seem worth while for me to take any notice of them, for the members of the committee are as well fitted as Mr. Bartlett to collect information on this matter. When, however, the legal representative of the Massachusetts Pharmaceutical Association puts his observations into a circular which is to give information to the medical profession, I feel called upon to straighten out his report a little in the interest of those physicians who are unable to inform themselves, as well as in the interest of the tax-paying public.

The preparation and distribution of antitoxin by the State Board of Health has been carried on very quietly and unostentatiously. Only last fall I met a physician practising in a prominent town of this State who had just learned of the free distribution of antitoxin by the State. When the work was begun over eight years ago there were but three plants in operation, all of them municipal. Two of these still survive. The work of the Board was considered more or less experimental in character, and everything was done in the simplest manner compatible with the safety and efficiency of the product. The rapidly increasing demand for antitoxin culminated in the epidemic of 1900, during which year over eighty thousand 1000-unit doses were distributed, equaling that many dollars in commercial value. The plant in the meantime remained experimental, but the product was no longer so.

It became evident, however, that if the work was to continue, provision must be made for adequate facilities, and the work must be recognized by the State. The present unsatisfactory arrangements made it necessary for me to give a great deal of personal attention to the work which would not be required with better equipment. Moreover, no work requiring the use of living bacteria could be carried on, and the manufacture of tetanus antitoxin carried on for three or four years was finally discontinued because I hesitated to bear the heavy responsibility. Yet with the present limited equipment a relatively enormous amount of antitoxin has been prepared—1,300 liters from Jan. 1, 1897, when a new method of recording amounts went into effect. This represents a market value of over \$250,000. So far as I know, this huge amount of fluid has been absorbed without any untoward effect. As stated above, for several years tetanus antitoxin was prepared side by side with it, and yet there is no record of any injurious effect. This shows that the safeguards were adequate, and in these safeguards the personal factor plays a prominent part. No matter how elegant and automatically perfect the equipment, things may go wrong, for the more we depend upon either living or automatic machinery, the greater the watchfulness demanded.

This much it seemed necessary to state concerning the operations of the Board in the preparation and distribution of antitoxin up to the present.

The circular sent out by W. W. Bartlett, representing commercial interest, was thus without a historical basis, even if its details had been on a level with the facts. That the equipment is unsatisfactory we all know, otherwise there would be no reason for legislation. That it was unsafe, not a shadow of evidence could be adduced to show, and the author had to fall back upon some Latin phrases and some ridicule of the city of Boston and of the State. It seems to me that if the State is to retain in its service men of self-respect, such extemporized inspection of public institutions must be forbidden. It is wrong on at least three separate counts. It was reported to the public at large, who are unable to judge in matters requiring professional and expert training; it was made by a man who possessed neither of these qualifications, as his remarks about antitoxin standards and filters reveal only too clearly, and it was full of misleading statements and misstatements of fact, the most serious being that he obviously tried to convey the impression that antitoxin was prepared in a stable. The fact is that the antitoxin is prepared inside of the horse, but next to the horse, the most important steps are those carried on in the laboratory. The stable and bleeding room play a quite secondary part in the whole matter. In spite of his assertion to the contrary, in the *Boston Evening Transcript* he opens his circular with the following sentence: "This biologic laboratory consisted of two very old and very dirty stables." He states elsewhere: "... and yet this very important serum that should only be prepared under the most careful aseptic conditions was made in this filthy stable." "When I contemplated that this great museum of comparative biology and bacteriology... really consisted of two unsanitary and filthy stables." He recognizes the existence of a laboratory later on, but through a peculiar psychological squint or after image effect the "two filthy stables" rise up to obscure the laboratory.

He recognizes the laboratory, in that he enters it with-

out being able to wipe his feet on a door mat. The laboratory is several hundred feet from the stable, and is guarded by four successive door mats. Why he did not see or use them I do not know, yet it would not have been the part of the laboratory assistants to invite a quasi-member of the Revision Committee of the United States Pharmacopeia to wipe his feet before entering.

I refer to these matters to show the pettiness of the criticism and its essential untruthfulness. I might analyze the circular line by line and show similar oddities in each sentence.

As the matter actually stands, no one officially connected with the work has claimed that the Board had a model plant or a plant at all. Of the many scientists who have visited me, there have been some who have been interested in the antitoxin work because of the success attending its use in the Boston City Hospital and in the State. There are always some who are interested to know what "Massachusetts is doing." To these I have always stated that the antitoxin plant was still in the experimental stage, and that there was nothing to be imitated, at present. It should also be remembered that legislation upon this subject has been pending for more than a year, and that under the circumstances I could not consistently recommend the outlay of money not absolutely necessary until such legislation had been completed. No one would welcome more than I a model plant which represented the simplicity as well as the high standards of our State, and to which all interested strangers would be welcomed. At the same time, we welcome whatever private manufacturers are doing to improve appearances and make their plants inviting to strangers. This, however, as the scientist well knows, is no guaranty whatever that the product is equally honest. That could only be ascertained by prolonged inspection and special tests.

The "inspection" made by the legal representative of the Massachusetts Pharmaceutical Association was unsatisfactory for other weightier reasons. No one can spend fifteen to thirty minutes in a laboratory, witness none of the processes, and yet claim to criticize them. In fact, a full week's attendance would have barely acquainted him (even if he were trained) with those processes which form the true safeguards of a biological product. This leads me to say something of methods. There are half-a-dozen successive safeguards in the preparation of serum upon which different men, with sufficient training and experience, would lay different emphasis, according to the conditions under which the serum is prepared. I should not be willing, for example, to follow the methods of one manufacturing firm, although I am prepared to admit that their final product may be as safe as any. The fact is that we must trust individuals, especially where the preparation of such things as "biological products" is concerned, and if these individuals are amenable to public authority and their methods open to investigation by properly constituted official bodies and no commercial or financial interests are involved, we are perhaps as safe as we can be among the uncertainties of life. Above all, any injurious results caused by such products would become known at once, which may or may not be the case with private products. I was told some time ago that a certain animal vaccine prepared by some firm killed all or nearly all the animals inoculated with it. The firm paid the damages, and nothing more was said about it. Think of the uproar which would follow the killing of a single cow with State vaccine! That accidents may now and then follow the use of antitoxin serum injected in such large amounts may be looked for with the other unexpected casualties of this world. Yet even here we must carefully weigh facts. It might be possible, to use an extreme illustration, to carry safeguards so far as to make the cost of serum prohibitory.

The public is always liable to be affected by externals and appearances, and private manufacturers are fully aware of this human quality. Even physicians fall under the influence of appearances, yet any one knows that they are only indices in the practice of medicine and surgery, and often very unreliable ones. I think it is important to emphasize this aspect of the subject brought out by Mr. Bartlett's letter. If the State Board of Health should be authorized to prepare certain biological products, to whose judgment of the necessary elegance of a

should they submit? This is a very essential question, for if such men as Mr. Bartlett shall be allowed to lay havoc in the public press with carefully planned arguments looking towards economy, efficiency and utility, rather than appearances, the plan of a public health might as well be given up, for I doubt that any well-meaning man would be found willing to direct the work under such conditions.

Arguments are sometimes presented in favor of large plants as compared with small plants. Here, again, the care of the manufactured product must be considered. The process of preparing antitoxin and vaccine were that required to make a pin or a nail it might be left to private competition or combination. There human element is eliminated by an unvarying machine. In the preparation of biological products there many variable factors requiring exercise of judgment constantly. The larger the establishment, the opportunity for any responsible director to control judgment on the part of a large staff of routine workers. In fact, biological products are of such a character that they cannot be introduced into the pharmacopeia, because no adequate tests can be provided for. The druggist, in the case of antitoxin, must appeal to the State Board of Health to make the test for length or sterility, and this body must, therefore, be prepared to maintain standards for such a purpose. The personal element is thus a very important factor, will remain so as long as these biological products are not be made artificially and by well-defined processes. The Vaccination Number of the *British Medical Journal* (July 5, 1902, p. 60) occurs the following passage which seems to fit present circumstances very well:

regards the private English firms which prepare animal vaccines, there appears to be a general anxiety to conform to most of the principles already laid down as necessary for obtaining a vaccine which, when taken from the calf, shall be as free as possible from extraneous organisms. There is only one comment which can be made upon their methods. As has already been pointed out, the essential condition upon which success depends is, at every stage of the process, the personal factor. If a bacteriologist with established reputation for accurate work is directly responsible for the entire conduct of the work, his name alone is sufficient to guarantee that every precaution is being taken against contamination. But the mere assurance that the work is being conducted under strict supervision or by trained experts does not give one the degree of confidence in it because the terms "supervision" and "expert" are somewhat vague and elastic. . . .

In conclusion I wish to point out the difference between a public and a private plant in their position as scientific institutions. The public plant finds in the advancement of science its chief incentive, the private plant finds the same necessarily in making money. Science is natural enough, and we would not quarrel with them if they did not wish to assume the rôle of scientific institutions and endeavor to suppress the public institutions. They have thus far not contributed anything of value to the problem of serum therapy and antitoxins. If they have, it is kept as a trade secret, and their scientist nor physician would be in a position to estimate its value. If we intend to maintain only private laboratories for the preparation of antitoxin, there is no reason why Professor Behring should not have been granted patent rights for his discovery. The manufacturers fought him most energetically, yet all the objections raised in this country against granting a patent are personified in the manufacturers in their endeavor to suppress public institutions. Progress can come only through laboratories aided by the universities by special funds and by public institutions authorized to prepare such biological products. The mentioned are in the best position for investigation, and thus far they have done most to further our knowledge of these valuable preventives and remedies.

Respectfully yours,

THEODORE SMITH, M.D.,

Pathologist to the Massachusetts Board of Health.

APRIL 15, 1903.

MR. EDITOR: The Committee of the Massachusetts Legislature, before which hearings were held recently on a bill proposed by the antivivisectionists, has given the petitioners leave to withdraw. X.

BOSTON, April 10, 1903.

MR. EDITOR: For some time I have had in mind asking, through the medium of your esteemed JOURNAL, what is the origin of the spring medicine idea, if I may so call it, which seems to prevail at this period of the year, but have omitted doing so for one reason or another. Some practitioners seem to countenance the custom, but I cannot seem to get any justification for it that appeals to reason. The popular mind has the idea so deeply graven upon it that it seems a hopeless task to combat it. The origin of the custom would prove interesting to

A CONSTANT READER.

Deaths reported, 3,466; under five years of age, 1,035; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 761, consumption 375, scarlet fever 42, whooping cough 55, cerebrospinal meningitis 10, smallpox 8, erysipelas 6, measles 32, typhoid fever 46, diarrheal diseases 18, diphtheria and croup 90.

From whooping cough, New York 4, Chicago 7, Philadelphia 13, Baltimore 1, Pittsburg 5, Providence 2, Boston 8, Springfield, Framingham, Salem and Fitchburg 2 each, Cambridge, Lynn, New Bedford, Haverhill, Malden, Taunton and Quincy 1 each. From erysipelas, Chicago 2, Philadelphia 1, Providence 1, Worcester 1, Cambridge 1. From smallpox, Chicago 1, Philadelphia 2, Pittsburg 4, Boston 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending March 21, the death-rate was 17.0. Deaths reported, 4,905; acute diseases of the respiratory organs (London) 282, whooping cough 111, diphtheria 72, measles 163, smallpox 12, scarlet fever 42.

The death-rate ranged from 9.0 in Kings-Norton, to 28.5, in Wigan; London 17.2, West Ham 15.5, Brighton 12.9, Portsmouth 12.0, Southampton 12.8, Plymouth 17.2, Bristol 13.2, Birmingham 19.4, Leicester 14.0, Nottingham 16.5, Bolton 18.3, Manchester 17.8, Salford 21.4, Bradford 15.3, Leeds 14.8, Hull 15.0, Newcastle-on-Tyne 18.8, Cardiff 13.9, Rhondda 18.3, Liverpool 19.4, Ipswich 15.2.

METEOROLOGICAL RECORD.

For the week ending April 4, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

| DATE | Barometer. | | Thermometer. | | Relative humidity. | | Direction of wind. | | Velocity of wind. | | We'th'r * | | Rainfall in inches. |

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE, FOR THE SEVEN DAYS ENDING APRIL 9, 1903.

MURRAY, R. D., surgeon. Granted leave of absence for fourteen days from May 1. April 6, 1903.

MCINTOSH, W. P., surgeon. To proceed to Lumpkin, Ga., for special temporary duty. April 5, 1903.

PIERCE, C. C., assistant surgeon. Detailed to represent the service at the meeting of the Florida State Medical Association to be held at St. Augustine, Fla., April 8-10. April 3, 1903.

ALTREE, G. H., acting assistant surgeon. Granted leave of absence for five days, from April 8. April 7, 1903.

RODMAN, J. C., acting assistant surgeon. Granted five days' leave of absence from April 8. April 7, 1903.

WALKLEY, W. S., acting assistant surgeon. Granted leave of absence for two days. April 5, 1903.

PROMOTION.

E. M. HOLT, pharmacist of the third class, promoted to be pharmacist of the second class, effective March 2, 1903. April 3, 1903.

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING APRIL 11, 1903.

C. BIDDLE, surgeon. Detached from the Navy Yard, League Island, Pa., and ordered to the "Minneapolis."

G. T. SMITH, surgeon. Detached from the "Puritan" and ordered home to wait orders.

C. D. NORTON, surgeon. Detached from the "Minneapolis" and ordered to the Navy Yard, League Island.

J. H. HALLOWAY, assistant surgeon. Detached from the Museum of Hygiene, and ordered to the "Franklin."

E. M. BROWN, assistant surgeon. Detached from the Museum of Hygiene, and ordered to the Nav. Hospital, Norfolk, Va.

D. P. MCCORD, acting assistant surgeon. Appointment revoked, to take effect April 4, 1903.

E. S. BOGART, surgeon. Ordered to the Naval Academy, Annapolis.

T. M. LIPPITT, assistant surgeon, retired. Detached from the Naval Hospital, New York, and ordered home.

C. F. KLY, assistant surgeon. Ordered to the Naval Hospital, New York.

SOCIETY NOTICES.

THE MASSACHUSETTS MEDICAL BENEVOLENT SOCIETY was incorporated in 1871 to carry into practical effect upon a larger scale the purposes of the Massachusetts Medical Benevolent Association, which dates from 1856.

ARTICLES OF ASSOCIATION adopted March 19, 1857.

"Whereas it sometimes happens that worthy members of the medical profession become reduced in circumstances, whose names are underwritten (all being residents of Massachusetts) do hereby associate ourselves as a body corporate for the relief of such especially as become members of this Society or of their families should they need assistance; and of such other members of the medical profession, or their families, as may be deemed by the Society suitable objects of its beneficence."

The present officers of the Society are:

DR. DAVID W. CHEEVER, *President*.

DR. J. C. WHITE, *Vice-president*.

DR. W. L. RICHARDSON, *Treasurer*.

DR. W. H. PRESCOTT, *Secretary*.

The names of those wishing to become members must be presented to the Secretary at least two months before the annual meeting, which is held in Boston, on the last Thursday in October. Any physician in good standing is eligible for membership. Blank applications may be obtained from the Secretary, Dr. W. H. Prescott, 285 Marlboro Street. Admission fee \$5.00, annual dues \$2.00, life membership \$25.00.

The Society now cares for sixteen beneficiaries. Its motives appeal to the medical profession, and this notice is published to solicit new members.

BOSTON, April 1, 1903.

ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES.

— The twelfth annual convention of this Association will be held in Boston, May 19-22.

BOOKS AND PAMPHLETS RECEIVED.

Essays on Clinical Medicine, being Reprints of Papers published at various times in the *American Journal of the Medical Sciences*. By Beverley Robinson, A.M., M.D. (Paris), Philadelphia: William J. Dorman. 1903.

Twenty-fifth Annual Report of the Board of Health of the City of Lowell for the year 1902.

Fifth Annual Report of State Hospital for Crippled and Deformed Children. St. Paul, Minn.

Pelvic Deformity in New York City. By James Clifton Edgar, M.D., of New York. From the Transactions of the American Gynecological Society. 1902.

Some Problems of Preventive Medicine. By Burnside Foster, M.D., of St. Paul, Minn. Reprint. 1903.

The Local Use of Iodine in Corneal Ulcers. By J. Lawton Hiers, M.D., of Savannah, Ga. Reprint. 1902.

Variations des Echanges Respiratoires, sous l'Influence de l'Altitude, de la Lumière, de la Chaleur et du Froid. By MM. Albert Robin de Paris and Maurice Binet of Saint-Honoré-les-Bains. Grenoble. 1902.

Twelfth Report of the State Board of the State of Maine for the Two Years ending Dec. 31, 1901.

Through Shot and Flame, the Adventures and Experiences of Z. D. Kestell, Chaplain to President Steyn and General Christian de Wet. London: Methuen & Co. 1903.

Transactions of the Obstetrical Society of London. Vol. XLIV. For the year 1902, with a list of officers, fellows, etc. Part IV, for October, November and December. Edited by Amand Routh, M.D., and Alban Doran, F.R.C.S.

Original Articles.

THE REACTION TIME OF CORROSIVE SUBLIMATE IN DIFFERENT DILUTIONS AGAINST VARIOUS SPECIES OF BACTERIA.

BY CHARLES HARRINGTON, M.D., BOSTON,
Assistant Professor of Hygiene, Harvard Medical School,

AND HAROLD WALKER, M.D., BOSTON,
Assistant in Hygiene, Harvard Medical School.

WHEN Koch, in 1881, gave to corrosive sublimate the first place as a disinfectant, stating that an exposure of but a few minutes to a 1:5,000 solution is sufficient to ensure the destruction of the most resistant organisms, and that with weaker preparations the results of longer exposure begin to be uncertain only when the dilution reaches 1:20,000, the object of all experimental work in disinfection was the discovery of the best agent for general purposes; that is, for disinfection of houses, ships, railway cars, furniture, hangings, linen, excreta and other vehicles of infection. The element of rapid action did not enter very largely into the experiments made at that time and considerably later; and, as a rule, the period of contact of the organisms with the poison was measured by hours rather than by minutes. The results of work by other investigators who followed Koch, and of Koch's later experiments as well, demonstrated that the original estimate of the value of the agent had been placed much too high; but notwithstanding this fact, corrosive sublimate has retained its place as the favorite and most reliable chemical disinfectant. Indeed, it appears that very many who employ it regard it as almost instantaneous in its germicidal action, without reference to the extent of its dilution; and the very common habit of immersing the hands in weak solutions for a few seconds and then proceeding to dry them, on the assumption that the brief contact has sufficed to kill all of the bacteria present, has led us to determine the length of time necessary to accomplish the destruction of a number of different species under the most favorable conditions with the dilutions commonly employed.

If one looks into the literature of the subject it will be observed that the number of species used in experimental work is not large — chiefly anthrax spores and *Staphylococcus pyogenes aureus*. These have been employed, as a rule, in the dry state on silk threads. It will be observed, too, that the subject of sterilization of the hands for operative work was, in the investigations which conferred the place of honor on this substance, not under consideration, and that only occasionally has the time of contact been measured by minutes and seconds. Differences in technique, in the strength of solutions, and in conditions generally, have led, naturally, to different conclusions; but unfavorable results have evidently been overshadowed by those which were confirmatory of the first estimate. The methods followed in many of the earlier investigations were such as would not now be employed. Thus, the threads were sometimes transferred after immersion in the disinfectant to solid media, upon which, in consequence of the presence of the accompanying poison at the point of contact, no growth would occur, although living organisms were present in the fibers; thus, a negative, rather than a positive, result would

be recorded. Again, broth cultures have been mixed directly with the disinfectant, in disregard of the consequent formation of precipitates of proteid compounds of mercury, which might encompass the suspended organisms. And again, in many instances, the threads employed have been washed in alcohol after treatment with the disinfectant and before planting, in ignorance of the fact that, under favoring conditions of moisture, this agent in various concentrations may exert a destructive influence very quickly.

In our experiments the cultures employed were made in bouillon, into which, at the time of inoculation, sterile silk threads about three quarters of an inch in length were introduced in sufficient numbers. After twenty-four hours' incubation, at 37° C., the infected threads were removed from the bouillon and divided into two equal parts, one of which was used forthwith, the other being returned to the incubator in a sterile Petri dish, and kept therein until dry. In the shorter exposures, the time elapsing from the instant of immersion of the threads in the disinfectant until the transference to sterile bouillon, or, in case of washing, to sterile water, was measured accurately by means of a stopwatch. In the longer exposures, the time was measured in the usual way. The tubes of bouillon in which the threads were planted after treatment were incubated at 37° C. for twenty-four hours, or longer if no growths had then occurred. All the experiments were conducted at room temperature.

The organisms employed included the following: *Bacillus pyocyaneus*, *Staphylococcus pyogenes albus*, *Staphylococcus pyogenes aureus*, *Bacillus coli communis*, *Bacillus diphtherie*, *Bacillus typhosus* and *Bacillus anthracis*. They were obtained, through the courtesy of Prof. H. C. Ernst, from the stock cultures of the Laboratory of Bacteriology of the Harvard Medical School, and were grown on agar for forty-eight hours, at the end of which time the bouillon cultures were made.

The solutions of corrosive sublimate used were 1:1,000, 1:5,000 and 1:10,000.

In the moist state the threads were used just as they came from the bouillon, but in order to determine what influence the presence of the very small amount of proteid material withdrawn with them might have by uniting with the corrosive to form inert protective coverings, one series of experiments was conducted in which the threads were carefully washed for forty seconds in sterile water. As will be observed, the results obtained in this series were not essentially different from those of the others. The dried threads were not washed, and the results obtained indicate that they did not need it.

Since, in case of negative results, it has sometimes been asserted that in the transference of the threads directly from the disinfectant to bouillon a sufficient amount of the poison to inhibit growth has been carried over, a number of tubes which showed no growth after forty-eight hours were inoculated directly and returned to the incubator. In every instance abundant growth occurred within twenty-four hours.

The results of the several series of tests with each organism are given below in tabular form. Growth is indicated by +; sterility by —. Where neither sign is given in any column, no planting was made.

In the statement of time, half-seconds are disregarded.

In order to save repetition, we will say here that each set of experiments was controlled, and that in every instance the controls grew luxuriantly.

From the above, we see, in the first place, how two cultures of the same organism may show a very great difference in resistance to the same solution, under exactly similar conditions of experimentation; and in the second, how the resistance is affected by a condition of dryness. So far as they go, the results indicate that dried *B. pyocyaneus* is killed by 1: 1,000 in less than 5 seconds, by 1: 5,000 in less than 15

Here, again, we observe differences in resistance on the part of different cultures of the same organism, and still more conspicuously is shown the influence of dryness. Whereas, the 1: 1,000 solution may not kill the moist organism in ten minutes, it destroys it in the dry state within three and one-half seconds; and although neither the 1: 5,000 nor

the 1:10,000 affects the moist organism in a half-hour, the former destroys it, when dried, within seven seconds, and the latter within a minute and a half.

The results yielded by the dried *Albus* would naturally lead one to anticipate similar ones in the

case of *Aureus*, but the above tables indicate how unsafe it is in problems of disinfection to reason by analogy and to employ the results of experimentation with one organism in generalizing as to others closely related. While *B. pyocyaneus* and *Staph. pyogenes albus* offer practically no resistance to 1:1,000 and 1:5,000 when dried, and are killed very shortly by even so weak a preparation as 1:10,000, this organism is not affected by drying, except in a slight degree. It succumbs a little more quickly to 1:1,000, but is quite as resistant as before to 1:5,000 and 1:10,000.

From the work with this organism we may conclude that 1:1,000 may be ineffective until between five and ten minutes' exposure, and that the other dilutions require, respectively, more than fifteen and thirty minutes' contact to produce sterility.

The diphtheria organism is shown to be very weakly resistant to 1:1,000, whether moist or dry,

From the results obtained with this organism, it appears that *B. typhosus* and *B. diphtherie* differ

but little in resistance in the moist state. When dry, the former is considerably more resistant than the latter to the weaker solutions.

DRY THREADS.

Culture A.

In this series the exposures to each solution ranged from ten seconds to thirty minutes in length. Luxuriant growth occurred within twenty-four hours in every one of the twenty-five tubes in which the threads were planted. Here, then, is another instance of the impossibility of reasoning by analogy in questions of disinfection.

We have seen five different species greatly affected in their power of resistance by a condition of dryness, and had it been that those were the only kinds employed, it would have been but natural to formulate a general rule that dryness always reduces resistance. But in the case of anthrax and *Staphylococcus aureus* the resistance is not changed at all.

GENERAL CONCLUSIONS.

(1) Different species of pathogenic bacteria, and different cultures of the same species, vary very greatly in their resistance to the action of corrosive sublimate.

(2) With some species, resistance is diminished in a remarkable degree by a condition of dryness, so that even the 1:10,000 solution can bring about sterility in a very short time. But some species are not materially affected in this respect by dryness.

(3) Corrosive sublimate in as weak solution as 1:5,000 is ineffective against the common pathogenic bacteria, including the pus organisms, when they are moist, excepting after prolonged contact. Since fifteen minutes' contact is not sufficient for the destruction of *B. coli communis*, *B. pyocyaneus* and *Staph. pyogenes albus* in the moist state, or of *Staph. pyogenes aureus* whether moist or dry, the use of this and of weaker preparations in surgical work and for irrigation and similar purposes should be abandoned.

(4) Corrosive sublimate in the 1:1,000 solution is very slow in its action on some of the commonest of the skin bacteria, and since under the most favorable conditions more than ten minutes' contact may be necessary for it to kill *Staphylococcus pyogenes albus*, it should not be relied upon to any great extent to ensure sterility of the hands or of instruments. The mere dipping of the hands for a few seconds into solutions of this strength can serve no useful purpose, but, on the contrary, can lead to much harm by inducing a false sense of security. In order to produce sterility of the hands through the use of this preparation, absolute dryness of the bacteria present would be essential; but a condition of the skin which would ensure such dryness would also ensure the bacteria not on the very surface against contact with the poison.

(5) Corrosive sublimate in any of the strengths commonly employed is a much over-rated disinfectant, and, under the best of conditions, is so uncertain in its action that it would be of advantage to abandon its use altogether in surgery.

THE CORTICAL CELL CHANGES IN EPILEPSY; THEIR SIGNIFICANCE AND CLINICAL INTERPRETATION.

BY L. PIERCE CLARK, M.D., NEW YORK,

Formerly First Assistant Physician at Craig Colony, Sonoma, N. Y.; Clinical Assistant in the Department of Neurology of Vanderbilt Clinic (Columbia College),

AND THOMAS P. PROUT, M.D., NEW YORK,

Formerly Second Assistant Physician and Pathologist at New Jersey State Hospital for Insane at Morris Plains; Clinical Assistant in the Neurological Department of New York Hospital.

WE do not intend to discuss at this time the voluminous literature on the pathology and pathogenesis of epilepsy. The lesion of epilepsy, as that of many other similar affections, has been placed in nearly every organ of the body. But investigations of the last ten years has definitely placed the point of beginning nervous discharge in the cerebral cortex.

In considering the pathological changes in epilepsy, a sharp distinction should be drawn between the lesions of the cortex, which are a direct result of the epileptic discharge, and those abnormal states of the cortex which precede and predispose the individual to epilepsy by producing an unstable nervous organism. As the paper will be confined to the former, changes consisting of prenatal causes, which are comprised in heredity and degeneracy, on the one hand and postnatal causative factors, such as trauma, cerebral palsy, thrombosis and the like, on the other, will not be dealt with. The more or less remote sequences of the disease comprised in chronic cell degeneration and gliosis, however tempting, will be taken up at another time. The morbid processes with which we are directly concerned are the earlier cortical lesions, the immediate sequence of the cortical poisoning and the epileptic fit.

The central idea which prompted the beginning of this study four years ago upon status epilepticus

¹ Preliminary communication to the authors' clinical and pathological researches upon Status Epilepticus; read before Boston Society of Neurology and Psychiatry, Mar. 19, 1903.

was that the latter is the most pronounced state of the disease. It has been aptly characterized as acute epilepsy. If, therefore, there are distinct cortical cell changes in epilepsy, such must be present in the most pronounced form following the status.

The study comprises an examination of the cortex in eighteen cases of epilepsy from the Craig Colony, seven of which died during status. Inasmuch as the postmortem changes in brain tissue interfere seriously with a clear judgment of the extent of pathological states, these changes were as far as possible eliminated by performing the autopsy at the earliest possible moment after death. In the eighteen cases studied the longest period of time elapsing after death before the material was placed in the fixing agent was seven hours; the shortest period was one hour. We are reasonably justified therefore in ruling out the question of postmortem changes in the tissues examined. The fixing and hardening agent was absolute alcohol, and the tissues were stained by the Nissl method, slightly modified to insure uniformity and to stain all the cellular elements of the cortex.

For purposes of comparative study some sections of normal brain were prepared in like manner to the pathological material, the sections being of like thickness, cut by the same instruments and stained in the same manner. The material itself was taken from a case of accidental shooting, dying instantly, which chanced to come into our hands, the tissue being placed into *absolute alcohol within two hours* after death.

The condition of the cells of the cortex, especially those of the second layer and other cells of that type, was most striking, and differed only in degree in the several cases of epilepsy. The cells were swollen, some being ballooned out to twice the normal size; the chromatic substance was almost entirely gone, nothing but a bare framework remaining of the body of the cell itself; the nucleus was often swollen out of proportion to the swollen cell body. In the majority of instances the outline of the nucleus was difficult to define, all traces of the nuclear membrane having disappeared. The nucleus itself presented a finely granular appearance, and in very many instances the nucleolus had been abstracted from the nucleus by the knife in making the section. This is brought about by the destruction of the intranuclear network, giving the nucleus its granular appearance and rendering the nucleolus a loose body within the nucleus, so that it is readily abstracted from it in the process of section making. It was a very frequent occurrence, especially in the status cases, in which condition the lesion was most pronounced; for example, in the last case of status examined, over one hundred and twenty examples of nucleolar abstraction were found in going over one square centimeter of surface in a single slide. The importance of this artefact will perhaps be better appreciated if it is stated that in examining through every portion of thirty-two slides of normal brain tissue this artefact occurred but six times.

We believe these facts point to a destruction and ultimate disappearance of the cell as a unit in the cerebral cortex. The involvement of the nucleus in a process which produces such vital changes in its structure is of most serious import. The nucleus

is the highest biologic portion of the cell; as an organ of the cell, recent biologic facts prove its high physiologic rôle. That it presides over the vital processes within the cell, and that without it the cell dies, are facts which are especially true of cells of the higher type.

We do not wish to be understood as interpreting these lesions as representing the final pathology of epilepsy. The conditions found in these cases indicate cell death, and teach us something as to the manner of its occurrence. The real pathogenesis of epilepsy, however, is to be sought, first, in those hereditary and acquired conditions which produce an unstable nervous organism, and, second, in those products of faulty metabolism comprised in the various toxic and autotoxic agents which act as excitants to a poorly developed nervous system.

We have refrained from discussing chromatolysis and cortical gliosis; it will not, however, be out of place to arrange these pathologic incidents of epilepsy in the order of their sequence as we conceive them. In order to do this, we must put together the facts of biology and histology. Inasmuch as chromatolysis in the last analysis is to be regarded as a nutritional change within the cell, and since the nucleus is the organ of the cell which presides over the processes of nutrition and assimilation, we must assume the action of some toxic influence upon the nucleus which determines the degree of chromatolysis. The order of sequence of the other changes found and usually described in epilepsy are of simple explanation. Since the nuclear changes ultimately result in cell death, we are in a position to better understand a condition so frequently found after status—the infiltration of the cortex with leucocytes. The gliosis, of course, occurs as a remote sequence of the cortical cell destruction, and since cells of the second layer suffer especially in the acute epileptic process, the great frequency of extreme gliosis in the outer layer of the cortex is readily understood. These facts are also in accord with the sequence of pathological changes in other tissues of the body.

The constancy of the lesion just described in all the varying states of epilepsy, from the mildest type to the severest climax of status itself, warrants the general conclusions of the significance of the epilepsy lesion. Epilepsy must be considered mainly a sensory phenomenon with a motor manifestation, which is practically the conclusion of Prus, Hering and Bischoff, from experimentally induced cortical fits. The disease is a highly organized sensory motor reflex of the cerebral cortex. This is proven not only experimentally and pathologically, but is susceptible of therapeutic demonstration.

The bromides appear to act upon the sensory, the afferent side of this reflex arc, either at the periphery or, what seems more probable, upon the sensory type of cells of the cortex itself. Bromides control the fits by reducing the intensity of afferent impulses to motor cells, which we believe to be immediately engaged in the cerebral discharge. When the bromides are given in toxic doses, acute and chronic poisoning is produced quite identical to the immediate and remote effects of the disease itself. Consequently bromides have been ungenerously burdened with the effects of the disease.

Bromides are but negative aids to cerebral inhibition.

Additional evidence of the essentially sensory character of epilepsy is shown in that bromides are of but little avail in those cerebral affections supposed to be largely motor in character, such as myoclonus, paralysis agitans, athetosis and post-epileptic disorders of motility. The anatomical and physiological integrity of the large motor cells in the cerebral cortex, even after a life long epileptic career which may end even in fatal status, is convincing proof of the autonomy of these elements. The immunity of these cortical elements from great structural change, aside from exhaustive shrinking, has caused pathologists to classify epilepsy with the neuroses, and vestiges of this nomenclature still remain. With attention still directed during the last decade to the motor cells of the cortex, the detection of glial overgrowth was urged as the initial histo-pathological change of the disease process, and thus obscured the truly initial change in cell nucleus.

Probably the most practical lesson to be drawn from the study is that epilepsy is a diffuse lesion of the entire cortex.

An order of muscular march in the fit shows only the successive order of spread of discharge in the motor centers, and this remains identically the same for years, almost without exception; yet the disease steadily undergoes important modifications, shown in a continuous destruction of cortical elements. The aura, which is probably always subjectively sensory in type, gives us definite information of the sensory changes. In its absence the degree and character of mental changes indicate the disease progress. Some convenient means of accurately recording the latter would aid much in diagnosis, prognosis and treatment. To the diffusion of the cortical lesion in idiopathic epilepsy must be ascribed the almost certain failure of surgical interference, although focal symptoms still remain. The coincidence, however, of sensory and motor symptoms both in the Rolandic area in acute traumatic cases largely explains the good results of surgical treatment in the absence of an hereditary predisposition.

The ultimate disappearance of the involved cortical cell element is the most serious clinical phase of its pathology. This fact explains many of the permanent symptoms of the disease, especially the slowness, awkwardness and inco-ordination of muscular movements, which amounts in many instances to paralysis in effect. The local and general exhaustion seen after local or general fits, especially in those parts which participate most in the discharge, are true exhaustion paralyses in type; but the chronic slowness, awkwardness and inco-ordination seen in long-standing cases are really of the sensory type in which the damage or loss of sensory elements not only permits cortical motor overaction as seen in the fit, but also leaves these motor elements uninformed of the normal nature and character of movements required. Analogous explanations hold good for tabetic ataxia.

The mental changes in epilepsy are analogous, but not commensurate, with the defective motility. However, to establish an adequate coefficient be-

tween the occurrence of fits and the degree of dementia is a difficult and complex problem.

Finally, we have in this study adequate evidence for the present empirical treatment of the disease in which the individual is given first attention. This consists, largely, to overcome hereditary tendencies and exclude toxic and autotoxic agents, in giving the patient a thoroughly detailed plan of diet, exercise, recreation, baths and sedatives comprised in the administration of bromides. In the light of the pathogenesis, the histo-pathological changes and their sequence which result in more or less prominent impairment of normal cerebral functions, the importance of the earliest treatment is obvious; the disease is also too profound in its changes for anything less than the most comprehensive attention.

In conclusion, we must say that the missing links of our knowledge of epilepsy consist in the fact that its pathogenic agents and the organic anomaly of the cortex, which constitute its predisposition, still hold the mystery of frequent relapses. By this study, however, we claim to have narrowed the gap between the terminal gliosis and the toxic and autotoxic agents in the disease pathogenesis, and we believe this is largely comprised in cell changes and those particularly of the nucleus.

DOUBLE UTERUS AND VAGINA.¹

BY C. H. HARE, M.D., BOSTON,

Gynecologist to Boston Dispensary and Woman's Charity Club Hospital and to Out-Patients at Carney Hospital and St. Elizabeth's Hospital.

Miss 2,370, age twenty-eight, single. A well-developed Scotch woman came under my care with the diagnosis of a discharging pelvic abscess needing freer drainage. Menstruation had always been regular and normal. There was at intervals free discharge of pus from the vagina which showed colon bacilli. There was also pus in the urine, though no bladder complaints. She was anemic with hemoglobin 50%, and heart murmurs. There was a question of trouble in the lungs.

Under ether the pulse soon passed 140, and became intermittent. The external genitals were normal. She had a tough normal hymen, and just inside it and to the right and anteriorly was what looked like a very small hymen, which admitted a probe one-half inch. What seemed otherwise like a normal vagina ended with a constriction the size of forefinger, beyond which was a small cervix and os, into which the writer could pass a sound only one and one-half inches. On the side of the above vagina just to the right of the median line anteriorly and beginning about an inch and a half from the hymen was a pouch into which the forefinger easily passed for two inches, where it met another cervix, into the os of which a sound easily passed two and a half inches. With a sound in each canal no touching was detected. By rectum the tubes and ovaries seemed normal, and there seemed to be a distinct fundus for each cervix both retroverted. No pus pocket was found, and owing to her condition further search was postponed. She gained

¹ Read before the Obstetrical Society of Boston, Feb. 16, 1903.

rapidly, and so satisfactorily to herself that she declined further investigation. Since leaving the hospital the writer has not been able to trace her.

Mrs. 374, an Assyrian, unable to speak English, of ordinary size and development, about thirty-five years of age. Married two months. Never pregnant. She came to my clinic at the Boston Dispensary May 5, with the story, through an interpreter, of abnormal flow and pelvic pain for four days. She refused to go to the hospital until May 13, when she entered the Carney Hospital, where the writer, owing to the kindness of Dr. Swift, had the privilege of operating and of reporting her case to-night.

The external genitals were normal. There was a double vagina, the right one perhaps slightly the smaller, with the dividing septum beginning about an inch from the introitus. There was a slightly smaller than normal cervix in each vagina. With a sound four inches in each os, no touching was detected. There were scant curettings, but free bleeding. The fundus was in good position, about the width of two, with a slight sulcus in the middle. Round ligaments and tubes came off as if from one normal fundus. There were general adhesions and double pyosalpinx. The appendix, both tubes and right ovary were removed. She had a very large and some six or eight inches too long sigmoid flexure, which was the first thing seen on opening the abdomen. Fresh smears from the tubes showed gonococci and a pure growth later. The husband told me he had gonorrhea five years ago, but was cured in fifteen days.

Among other peculiarities her left breast was covered with a flabby, tough, reddish-brown skin, several times the needed size; this condition extended upon the left arm from the breast and a similar small area of the same was upon the right breast. There were also queer patches upon the skin in other places, especially on the legs and feet. Two doctors from the Skin Department saw her, but had not seen such before and had no opinion to submit.

Dr. Storer can tell you the subsequent history of this case.

Mrs. 445, a third case, came to the writer because of dysmenorrhea and dyspareunia. She was seventeen years and eleven months old. Had been married nine months. Never pregnant. Menstruation began at fifteen, yet had never been regular, but occurring as a rule every six to twelve weeks, when she would flow from five to ten days, using about two dozen napkins and having some clots. Dysmenorrhea has kept her in bed during menstruation from its beginning. She had been operated under ether two years previously for her dysmenorrhea, but without any benefit. She had had "convulsions" since the age of two, and for some years a distinct hysterical story. She was in fair general condition, weight 115 pounds, which was a gain of 17 pounds in nine months. The clitoris and labia minora were unusually large, labia majora normal. There was a double vagina, with septum the entire length. Both were good size with the right perhaps a little the larger. There was a small cervix in each. The right canal measured two inches, the left two and a half. There seemed to be one ante-flexed freely movable fundus.

A fourth case of double vagina and cervix was seen by the writer in Quénu Clinie in Paris which, to look at, was exactly like my second case. Quénu was dividing the septum, and said there was a double fundus, but the abdomen was not opened that day.

A fifth case was examined with and seen, operated upon by a colleague. She was a large, well-developed woman. Married seven years. Never pregnant. External genitals were normal. There were no evidences of hymens. To inspection and touch the vaginae and cervices were like my second case, except the septum began at the introitus. Each canal was three inches, and no touching with a sound in each. There was really one broad fundus, though there were two distinct knobs with a marked sulcus anteriorly and posteriorly. Both tubes were normal, and like the round ligaments came off as if from a normal fundus. The right ovary was normal. A lemon-size cyst of the left ovary was removed, and a suspension done for a retroversion.

A CASE OF UTERUS BICORNIS DUPLEX, WITH TWO CERVICAL CANALS ABOVE, ONE EXTERNAL OS AND STRICTURE OF VAGINA.¹

BY W. L. BURRAGE, M.D., BOSTON.

M. C., single, thirty-one, a native of Prince Edward Island, first came under observation at the Carney Hospital in May, 1895. She complained of constant backache, worse at the catamenia, burning pain in the abdomen extending into the hips and down the thighs, and lasting for two weeks before each monthly period. Pain relieved on the appearance of the flow. She also had swelling of the feet, palpitation and dyspnea, leucorrhea constant. Catamenia every twenty-eight days, ten to twelve napkins, well soaked. Frequent micturition.

The diagnosis was made of endometritis and stenosis of the vagina, the vagina being constricted in its upper portion so that the opening admitted only a probe. The vagina was dilated, and the uterine curet, and a rubber plug left in the vagina.

In 1898 the patient again applied for treatment at the hospital, having had only temporary relief.

She was etherized again, the stricture was dilated and the uterus was curetted, a large amount of hyperplastic tissue being obtained.

Additional symptoms at this time were tenderness in the groins on going upstairs, fainting spells just before the catamenia, and headaches. Her occupation was children's nurse, and she found it difficult to follow it.

Jan. 23, 1903, she entered the Carney Hospital for the third time, and came under my care. She had not been well since she was last in the hospital. She had more pain in the right side than in the left, and during the two weeks preceding each period attacks of abdominal pain lasting for twenty to forty-five minutes, and coming on half an hour to four hours apart. Vaginal discharge enough in amount to necessitate wearing a napkin, thick and yellow in color.

Examination showed a well-developed and nour-

¹ Read before the Obstetrical Society of Boston, Feb. 17, 1903.

ished woman of dark complexion, tall and well formed. External genitals normal; vagina normal in its lower course, narrowed at a point 2 cm. below the cervix, so that it barely takes the tips of two fingers; cervix small, and situated in the right posterior portion of the pelvis; os single and of good size. The abdominal walls were rigid, and the shape of the uterus was difficult to make out, because of the rigidity of the walls and the situation of the uterus, which was fixed far back near the right sacro-iliac synchondrosis.

The sound went upward into the uterine cavity (probably the right one) a distance of two inches. An abdominal operation was performed Jan. 27, 1903, for the purpose of exploration and relief of symptoms. On opening the abdominal cavity it was seen that the uterus was double, as shown in the specimen, and adherent near the right sacro-iliac joint. Although the ovaries and tubes appeared to be normal, it seemed best to remove the uterus in view of the persistence of the dysmenorrhea, notwithstanding two curettings and much treatment extending over eight years. The patient desired to be relieved at any cost.

Accordingly supra-vaginal amputation was performed in the usual manner. When the uterus was amputated at about the middle of the length of the cervix, two distinct canals were found, as shown in the specimen, the stump of the cervix being broader than normal.

The patient is now, Feb. 17, convalescing.

Examination of the specimen shows the two ovaries and two tubes normal in appearance; the uterus cleft about half the distance from the fundus to the internal os; two separate uterine cavities extending downward nearly to the external os; several fibroid nodules imbedded in the substance of the uterine tissue, and much soft tissue lining each uterine cavity.

PREGNANCY IN A UTERUS BICORNIS SIMULATING EXTRA-UTERINE PREGNANCY.¹

BY FRANK A. HIGGINS, M.D., BOSTON,

Instructor in Obstetrics, Harvard Medical School; Senior to Out-Patients, Boston Lying-In Hospital; First Assistant Visiting Physician for Diseases of Women, Boston City Hospital.

Cases of double uterus or of uterus bicornis are not very rare. They are much more common than generally believed, probably they are of more frequent occurrence than any other congenital anomaly of the female pelvic organs. Undoubtedly many cases are never recognized. In going over the literature of the reported cases, one is impressed by the fact that many of these cases are discovered only by accident. It is fair to presume, then, that the average case gives rise to no symptoms whatsoever, and if occasion did not arise from other causes, for some form of operative measure in the pelvis, many cases would remain unnoticed indefinitely. Those forms of double uterus, in which the septum is continued into the vagina, are naturally more commonly observed in married women, because they occasionally give rise to difficulty in intercourse, and then again they are likely to be discov-

ered in making vaginal examinations in the course of labor. Yet cases of double uterus are frequently reported, in which a patient has passed through several perfectly normal labors, until finally, in a subsequent labor, the abnormal condition becomes evident, although giving rise to no obstruction to delivery. In reading the reports of recently published cases the writer was impressed by the comparative frequency of twin births in connection with the various forms, partial and complete, of double uterus. Attention to this may have been called before; if so, it has not been noticed, neither is the fact explained. It may have been merely a coincidence in these cases.

Pregnancy in one horn of a uterus bicornis has, in a number of instances, been mistaken for extra-uterine pregnancy, and that the differential diagnosis, except in particularly favorable circumstances, is oftentimes impossible, is generally well known.

The writer has operated upon two cases of uterus bicornis. In the last one, the subject of this paper, the abdomen was opened with the expectation of finding in a large and rapidly-growing tumor a tubal pregnancy. The patient was first seen by me at my office on Sept. 9, 1902. The history is interesting and instructive. Mrs. A., thirty years, married seven years, one normal full-term delivery five years before; two premature, four and three years ago, both accidental. The regular menstrual period was from May 29 to June 3, 1902. On June 18, at a private hospital, she had an operation for repair of the cervix and a curettement. She did not flow again until six weeks after operation, and then flowed for six days profusely. She stopped two days, commenced again and continued four or five days, on the second day passing a clot the size of an egg. Since then she continued to flow nearly every day until the operation. Blood was dark and many clots were passed. No pain, chills or fever, but had considerable nausea. She had been seen and examined by the physician who performed the cervix operation, who believed that there was an extra-uterine pregnancy, and advised operation.

On examination I found the uterus not increased in size, but crowded down into the pelvis and somewhat to the left, while in the abdomen above the pelvis could easily be felt a rounded mass somewhat to the right side and apparently connected with the uterus. This mass was rather soft, and resembled in consistency a pregnant uterus or a cyst, was about the size of an orange and seemingly containing fluid. The patient stated that she had not been with her husband since her operation of June 18. She was a Jewish woman, and if pregnancy existed, conception must have occurred in all probability some time between June 10 and 17. In view, then, of the mass on the right connected with the uterus, the repeated hemorrhages and the continued nausea, it seemed that the diagnosis of extra-uterine pregnancy of three months' duration was comparatively easily established. Moreover, the fact that the uterus had been curetted and the cervix repaired since sexual intercourse had occurred, would seem to exclude the possibility of an intra-uterine pregnancy. The fact that the pregnancy was not made out at the time of the cervix operation was not to be wondered at, because of the short time, probably not over a week, since conception. A

¹ Read before the Obstetrical Society of Boston, Feb. 17, 1903.

pregnancy of this short duration would scarcely make any noticeable difference in the size, even of a normal tube, when palpated through the abdominal and vaginal walls.

The patient was referred to the City Hospital, where a review of the history and a second examination only seemed to confirm the previous diagnosis. On opening the abdomen an oval mass about four inches in diameter, slightly to the right, was found. It had every appearance of the normal pregnant uterus, except that the left tube and ovary were then not seen in their normal positions, while the right tube and ovary were absolutely normal. On reaching deep into the pelvis on the left side, the tube and ovary were found, the ovary being normal. The tube in its outer two thirds was normal, but the inner third apparently suddenly enlarged, and was continued in its normal shape as a hard body about one-half inch in diameter and one and a half inches long, and ending at the uterus just above the internal os. The question at once arose whether the apparent enlargement of the tube was the small cornu of a uterus bicornis, or a fibroid enlargement of the tube. The latter condition is rare, but the fact that the tube ran directly into the end of the mass and not at one side, as would be expected if the body was uterus, seemed to make its removal advisable. It was accordingly dissected out at the uterine surface by a V-shaped incision, and the uterus closed in. Through the center of the body was a canal continuous with the lumen of the tube. The tumor was firm and dense, and was found by the pathologist to be uterus.

The patient recovered without reaction. She was kept in bed for four weeks in order to give the abdominal wall extra time to become firmly united, in view of the strain which was soon to be put upon it by the growing uterus. At the time of the patient's discharge from the hospital, pregnancy was about four and one-half months advanced, and there were no indications of an abortion. There was no further hemorrhage after the operation. Why the patient should have had so much flow during the early months of her pregnancy I am unable to explain.

I have no apology to make for the diagnosis or for the operation. As was stated in the early part of the paper, similar instances have been reported before under more or less similar conditions. The fact that the uterus had been curetted and the cervix repaired, after conception had occurred, would appear to exclude the possibility of an intra-uterine pregnancy. We must assume, therefore, that it was the left cornu of the uterus which was curetted, while the ovum was lodged in the right cornu. The two operations serve to demonstrate the remarkable tolerance of the pregnant uterus, in many cases, to operative procedure.

It has been repeatedly pointed out that with a rapidly-growing tumor to one side of and distinct from the uterus, with an irregular discharge of blood, and without the presence of any of the other so-called typical symptoms, the diagnosis of extra-uterine pregnancy should be made. The differential diagnosis of pregnancy in a uterus bicornis, from extra-uterine pregnancy, is oftentimes impossible except when the condition of the pelvis is known before.

Medical Progress.

PROGRESS IN THERAPEUTICS.

BY ELLIOTT P. JOSLIN, M.D., BOSTON.

IMMUNIZATION OF CATTLE TO TUBERCULOSIS.¹

In a former report on Progress in Therapeutics we referred to v. Behring's work on the protective inoculation of cattle with dried human tubercle bacilli. V. Behring has continued his studies and experiments, extending their scope. On March 12, 1903, he announced in Vienna that he considered the immunization of young cattle to tuberculosis by his method as established. Henceforth he will devote his energies to the study of immunization in man. An abstract of the paper follows, but the reader will be well repaid by a perusal of the original communication. V. Behring is more convinced that the results which he has obtained are definitely useful than he was eight years ago, when he announced in the same city his work on Diphtheria Antitoxin.

Dried human tubercle bacilli are injected into one of the cervical veins. The bacilli were obtained from a laboratory culture eight years old. Four thousandths of a gram emulsified in 4 cc. water are employed for an initial dose. The injections give rise to a reaction varying with the age of the animal and apparently with the presence in it of some tubercular infection. The reaction increases in intensity with the age of the animal; very young animals are not at all sensitive. Fever and anorexia usually occur on the day following the injection, and in many animals persist for a week. Such animals either were tuberculous, or tuberculosis was suspected. Cattle more than one year old react alarmingly to the injections. They become dyspneic, present the signs of pulmonary edema, and a serous effusion in the pleural cavities appears. Death occasionally occurs. As a rule, after a few weeks these symptoms disappear, and if the animals are killed all traces of disease are absent. If the animals are killed at the height of the reaction, a pleuro-pneumonia with tubercle bacilli is found. The hypersensibility of such animals to the injections goes hand in hand with the power of their blood to agglutinate tubercle bacilli and with a positive tuberculin reaction. Behring interprets these phenomena as proof that such hypersensitive animals have suffered a tuberculous infection, even though they show no tuberculous focus. Protective inoculation is therefore contraindicated in animals over one year old, because they so often have been infected with tuberculosis. Calves under three months are the most favorable subjects.

In an earlier communication v. Behring showed that calves immunized with human tubercle bacilli were proof against direct inoculation with bovine tubercle bacilli. To test the immunity in another way, in the last year and a half he has kept immunized calves in stables with cattle in advanced tuberculosis. Several of these calves have been killed, and no tuberculous foci found. Antopsies have also been made on immunized cattle which have been distributed during this time in agricul-

¹ Berl. klin. Woch., March 16, 1903, p. 233.

tural communities, and in no instance was tuberculosis discovered.

Fourteen cattle, shown to be free from tuberculosis by the tuberculin test, were exposed for one year to tuberculosis in a stable. Three of these fourteen cattle were previously immunized. At the end of one year these three cattle showed no tuberculin reaction, but the reaction was positive in all the other cattle. Further tests with tuberculin must, of course, be made to determine the duration of the immunity.

It will naturally be impossible to immunize children in the same way as calves; instead, v. Behring will seek to attain the same result by the use of anti-bodies. In infancy infectious material as well as anti-bodies are readily absorbed. Making use of this fact, v. Behring will attempt immunization by the use of milk obtained from immunized cows.

In conclusion, he comments on the usefulness of sanatoria, especially those which are designed for advanced cases of tuberculosis; on the rapidity with which the sanitarium idea has spread; on the possibility that we are increasing the number of tuberculous individuals in our community by prolonging the average duration of life of such individuals; on the futility of preventing infection even by better dwellings for workmen; on the dangers to which new-born children are exposed by contact with tuberculous parents.

KOCH'S REPORT ON METHODS OF COMBATING TYPHOID FEVER.²

Klemperer in this article summarizes Koch's Collective Investigations on Typhoid. Typhoid has diminished in cities, but not notably in country districts, because there the feces are used on the soil and privies are even in direct contact with the dung heap. Inevitably some of the feces are tracked into the house.

There are two conditions which must be fulfilled for successful treatment of an infectious disease: (1) The discovery of the infectious material must be easy and sure; (2) The infectious material must be destroyed. The first condition is not met by the Widal test or by the demonstration of the presence of typhoid bacilli in the stools. The former reaction often occurs too late, the latter is impracticable. Two of Koch's assistants, however, — v. Drigalski and Conradi, — have discovered a procedure which enables a positive diagnosis to be made within twenty to twenty-four hours. The method is only suitable for use in a laboratory. It depends on the selection of a medium favorable to the growth of typhoid bacilli but inimical to other intestinal bacteria, and takes advantage of the acid-forming qualities of colon and typhoid bacilli.

(2) It is an easy matter to destroy typhoid bacilli in the stools, but are we sure that they exist only in man? Koch thinks that we are. The more he has studied the question, the more he has become convinced that they do not live for long periods in water and soil. The epidemics which he has investigated show an infection from case to case. The typhoid bacilli, like the malarial parasites and cholera bacilli, are obligate parasites, and though the typhoid bacilli can perhaps live longer outside

the body than the cholera bacilli, they are finally destroyed.

An epidemic of typhoid was investigated at Trier. Eight cases were reported, but by diligence in investigations seventy-two cases in all were discovered. Of these seventy-two cases, fifty-two were in children, and of these only three had been reported. Koch explains the few cases in adults on the ground that in childhood they acquired an immunity; the many cases in children are due to their mode of life exposing them to infection. In this epidemic water had nothing to do with the spread of the disease. It was transmitted from one person to another. The epidemic was finally conquered by isolating all the patients and allowing none their liberty until the typhoid bacilli had disappeared. At the end of three months the epidemic ceased. One institute has already been founded to study the typhoid fever problem and to combat the disease when found. Two other similar institutions will soon be established. Koch considers that this same method of isolation is the one to be pursued with diphtheria and tuberculosis.

THE DIAGNOSTIC AND THERAPEUTIC USES OF TUBERCULIN.³

Moeller and Kayserling have observed no harmful results in an experience based on 3,000 injections of $\frac{1}{10}$ mg. to 1 gm. tuberculin. The old tuberculin was used for diagnostic purposes. The injection was made with a Luer-syringe between the shoulder blades. Fever, even the slightest, night sweats and hemorrhages were contraindications. They began with 0.1 mg. and a rise in temperature of $\frac{9}{10}$ of a degree F. (0.5 C.) counted as a reaction. Injection was performed in the evening in order that the temperature might be accurately measured in the morning. If no rise in temperature occurred, at successive intervals of three days the dose was raised to 1, 5, 10 mg. Not until this point was a reaction considered negative. Patients were kept in bed if the reaction exceeded 100.4 F. (38 C.). Acute cases as a rule reacted with small doses more actively than chronic cases.

The authors treated therapeutically twenty-six cases with old tuberculin and twenty-two with new tuberculin. An advanced stage of the disease and poor general condition with emaciation were contraindications. The initial dose was 0.1 mg. old tuberculin, increased every third day by 0.1 mg. or 0.2 mg. The dose was lowered in case of a reaction, otherwise increased to 0.5–1 mg. As a rule, at the end of one month 10 mg. were reached. Having overcome the first susceptibility, the dose could be quickly increased by 5–60 mg. The course of all these cases was favorable. New tuberculin was employed in the same doses, but with still greater care, being increased only with gain in body weight. The indications for the different tuberculin preparations are not yet defined, but no doubt can exist as to their therapeutic value.

OXYGEN INHALATIONS.⁴

The doubts which the physiologists and pharmacologists have expressed concerning the usefulness

³ Cent. für Inn. Med., 1903, March 7, p. 270.

⁴ Rev. in Cent. f. d. med. Wissenschaften, 1903, Feb. 28, p. 145.

² Die Therap. der Gegenwart, 1903, p. 74.

of inhalations of oxygen have lessened the employment of this remedy. This has led Von Leyden to reopen the question and Rogovin to publish two clinical and experimental studies upon the subject. Koryani explained the action of oxygen in conditions of cyanosis and dyspnea by experiments in which he proved that the accompanying increased osmotic tension of the blood serum could be lowered to normal by means of inhalations of oxygen. Increased absorption of oxygen takes place without doubt from an atmosphere rich in oxygen. The quantity of oxygen in the blood serum can be raised with pure oxygen four times and more. This is a matter of vital importance in severe anemia. Oxygen is indicated when the blood fails to be sufficiently saturated with it in the lungs and enters the left heart and the general circulation more or less venous in character. Rogovin has observed its favorable action in the diminution of cyanosis and in the lowering of the rate of the respiration and pulse. The volume and regularity of the latter were also favorably affected, and it was noteworthy that the quantity of the urine rose too.

The therapeutic employment of oxygen in cases of poisoning was studied in animals. In strychnia poisoning, for instance, the continual use of oxygen lowered the increased reflex excitability, and directly appeared to save life. The result was by no means so favorable in morphine poisoning, but still good. Toxic symptoms appeared later and in less intensity in those animals which inhaled oxygen, and they remained longer alive. The same held true for chloroform, illuminating gas and anilin poisoning.

TREATMENT OF OBESITY.⁵

Kisch recommends the following diet and *régime* in the treatment of obesity. Between 5 and 6 A.M. three or four glasses of water containing Glauber's salts at intervals of fifteen to twenty minutes. Thereafter one to two hours' exercise (walking) systematically and gradually increased. *Breakfast*, one cup coffee or tea without milk or sugar, or with a dessertspoonful of milk; 50 gm. (1½ oz.) zwieback, neither fat nor sweet; and 35–50 gms. lean ham or other meat.

During the forenoon a salt bath, rich in carbonic acid, at 80°, for fifteen minutes, followed by a cold rain douche over the whole body except the head; one hour's walk. With an intact and strong heart, twice a week a steam bath followed by a cold rub, douches and packs. One hour before the noonday meal one glass Sauerling with the addition of unsweetened lemon-juice.

1–2 P.M. *Dinner*: Generally no soup; 150–200 gms. roasted lean meat of the most hearty sort (except pork and goose) or fish (except salmon); 25 gms. zwieback, 50–100 gms. vegetables selected according to taste, except potato; fresh fruit for dessert, one or two small glasses white or light red wine; no water.

Afternoon. A long three hours' stroll — mountain climbing — during which is taken a cup of coffee or tea without sugar or milk. At six o'clock a glass of water containing Glauber's salts.

7–8 P.M. One hundred and fifty grams of a warm roast or cold meat or lean ham with vegetables

or stewed fruit prepared without sugar; 15–20 gms. zwieback. This is followed by an hour's walk, and occasionally by general massage. A cold bath or rub before retiring. Not over seven hours' sleep.

The above diet amounts to 160 gms. albumen, 11 gms. fat, 80 gms. carbohydrates.

The walks should cover twenty to twenty-five thousand steps measured by the pedometer.

The amount of calories and of exercise must be regulated for each patient according to the degree of adiposity, the age, stature, customs, condition of the blood and heart. During a four to six weeks' "cure" a patient should lose 6.5% body weight. The loss of weight shows first in the breasts and neck, then in order the chin and face, thighs and arms, buttocks, and last of all the abdomen. The heart can be controlled by carbonic acid baths, and the nervous system of the patient and his spirits by a change of scene. Exercise favors the albuminous metabolism.

(To be continued.)

Reports of Societies.

NEW YORK NEUROLOGICAL SOCIETY.

STATED MEETING Feb. 3, 1903, PEARCE BAILEY, M.D., President.

PARADOXICAL PSEUDO-HYPERTROPHY IN INFANTILE CEREBRAL HEMIPLEGIA.

DR. L. PIERCE CLARK presented a boy of ten years with a family history of epilepsy, insanity, alcoholism, rheumatism and tuberculosis. The personal history was good, except that when five years old he had suffered from a severe attack of smallpox. This had been followed by infantile cerebral hemiplegia, the convulsions being general and lasting for hours. A left hemiplegia was noticed the day after the convulsion. Three months after the initial stroke he had *status hemiplegicus unilateralis* attended by high fever. There were forty-seven *grand mal* fits in four hours. At present there were from three to five epileptic attacks daily with an epigastric aura. Hypertrophy of the calf on the paralyzed side was first noticed three years ago, but the left arm was moderately atrophic. The ankle also showed bony hypertrophy, a still rarer condition.

A CASE OF MYOCLONUS.

DR. CLARK presented a Jewish boy of eleven years having a negative family and personal history. Two years ago, without known cause, a spasm developed in the left biceps, triceps, pectoralis major, latissimus dorsi and sternomastoid muscles, and in a few weeks the same muscles in the right side became involved. The spasm was clonic in character, and occurred from twenty to forty times a minute, with never more than a few minutes of entire freedom from the spasm. In a few months the muscles of the pelvic girdle became affected, particularly the glutei, quadriceps and sartorius. Arsenic had been of no avail in suppressing the spasms. No spasms had been observed in the fingers or toes. The musculature was good, and there was no atrophy or sen-

⁵ Therap. der Gegenwart, 1903, p. 57.

sory change. All the reflexes were normal. The diagnosis of myoclonus was made on the bilateral, clonic, lightninglike character of the spasms of the proximal muscles.

A CASE OF MULTIPLE NEURITIS WITH INTACT REFLEXES.

DR. CLARK also presented this case, a child of five years, an imbecile and possibly epileptic. The boy had apparently had an attack of meningitis last July. He now presented the high-stepping gait and the exaggeration of all the reflexes. There was a marked diminution in the response to the faradic current. At present he was in the recovery stage of multiple neuritis, apparently of lead origin.

DR. J. RAMSEY HUNT asked if in the case of myotonia there was a history of fright; also if the term "myoclonus" was used in the generic sense. The case had much in common with Henoch's chorea.

DR. W. M. LESZYNSKY asked on what basis it was concluded that the multiple neuritis was due to lead. The distribution corresponded more to that of alcohol, and from the fact that the child had been taking beer, the probability was that it was an alcoholic neuritis.

DR. CLARK said that he looked upon the case of myoclonus as of the Friedreich type. The history of fright usually had to be taken with a good deal of allowance. He did not think it could be of the choreic type referred to because muscular atrophies occurred and ran a rapid course. The condition was not improved by the usual treatment for chorea. The case of multiple neuritis was first thought to be one of alcoholic origin, and an effort was made to obtain such a history, but the history of beer drinking was not at all satisfactory or definite. The child had been playing around a cellar, and had freely dabbled in lead paint a short time before the illness.

DR. PEARCE BAILEY thought the sharp, shocklike contractions of the muscles and the peculiar sound emitted by the boy should lead one to think of the type of electrical chorea.

A CASE OF MYOKYMIA.

DR. R. M. DALY presented a man of twenty-eight, a printer by occupation. There was no history of lead colic, and no family history bearing upon the case. For years he had engaged freely in athletic sports. About one year before coming under observation, after having walked for eleven hours, the calf muscles began to twitch. When first seen, last October, his general condition was good, as were also his habits. His gait and station were normal, and there was no paralysis of the muscles. Facial innervation was more marked on the right side. There was a fibrillary twitching of all the muscles of the legs and of the posterior muscles of the thigh. Sometimes the same bundle of muscular fibers would contract several times in succession. A blow upon the muscles brought out the contractions well. The electrical contractions were negative. There had been no evidence of atrophy during the time the patient had been under observation. There was no disturbance of the special senses, and the superficial reflexes were undisturbed. The knee jerk was increased; there was no clonus or Babinski. He had received increasing doses of strychnia and arsenic, galvanic and x-ray treatment, but all

without benefit. Quite recently he had been placed on gelsemium, and the twitchings had diminished somewhat.

DR. C. L. DANA said that while the condition was neither important nor grave, he thought it was of interest to recognize it as a distinct symptom. Fibrillary twitchings were common enough in states of exhaustion of any kind. Myokymia occurred in neurasthenic states, and sometimes also in alcoholics.

NON-SEPTIC CEREBRITIS.

DR. HARLOW BROOKS read this paper, reporting a case. He said that these cases had not been frequently reported in recent medical literature, and hence the case he had seen seemed to be worthy of reporting. The disease was not so very rare, but it was the exception for it to be recognized because of our scanty knowledge regarding it. Microscopical examination, in a considerable number of instances, had been found to be the only certain method of recognizing the condition. A considerable number of cases recovered wholly or partly. The cases going on to recovery were apt to be set down as examples of hysteria. Metabolic poisons and those toxins produced by the growth or action of bacteria should be just as competent to produce inflammation as injuries. In all inflammatory diseases the question of the occurrence of hemorrhages depended upon the severity of the inflammation and the situation of the lesions. He had no sympathy with those who insisted that an inflammation was necessarily dependent upon bacteria or their products. Acute encephalitis might terminate in death, if the disease involved parts of the encephalon essential to life. When complete recovery ensued it was probable that the inflammatory products were almost completely absorbed. When there was only partial absorption there would be more or less impairment of the functions of the brain. Such a condition not infrequently occurred in alcoholics or after severe attacks of insolation. The following case was then reported: The patient was a girl of nineteen years, by occupation a domestic. There was a history of headaches and bilious attacks. She was naturally rather dull. On the night previous to her entrance to the hospital she appeared to be as well as usual, but was found unconscious the next morning, and was thought to be suffering from poisoning. On admission, she was unconscious, and the respirations were stertorous. In response to pin-pricks the hands and feet were withdrawn. The pupils were moderately dilated, and reacted somewhat irregularly to light. She was unable to swallow, and did not respond to the usual forms of stimulation. Kernig's sign was absent. On Oct. 21, or two days later, the urine was normal except for a trace of albumin. The temperature varied between 100 and 101° F. Two days later some casts were found in the urine. On Oct. 25 a bed sore appeared to be forming over the sacrum, and the temperature was rising. There was a leucocytosis of 14,000. On Oct. 27 the patient took 2 oz. of water by mouth, but with this exception all nourishment had been by rectum. On Oct. 30 she spoke once, as she had done on the previous day. The bed sore was getting rapidly worse. On Nov. 1 she spoke rationally, and complained of

pains all over. Some nourishment had been taken by mouth. She was very uneasy during the night. On Nov. 6 the temperature varied between 102° and 105°, and the pulse between 140 and 160. She died with a temperature of 106° F. Several blood cultures were taken before death, and these proved negative. An examination of the eyes was also negative. The necropsy was begun two hours after death, and was conducted by Dr. Janeway. Nowhere in the body was there any inflammation except, of course, in the bedsores. Slight cerebrospinal meningitis was found of the cellular type. There was also a general non-septic cerebritis, most marked in the cortex and particularly in the motor area. There was degeneration of many of the ganglion cells in the cortex, apparently of recent origin, and of many of the fibers arising from the large pyramidal cell layer of the cortex. There was diffuse degeneration of many of the fibers passing through both internal capsules, and limited to no particular portion of the capsule. There was inflammation of the tissues of the cerebellum, though to a much less degree than in the cerebrum. There was degeneration of many of the descending fibers of the pons and medulla. There was also degeneration of the chief descending tracts of the spinal cord, and of some of the fibers in the ascending tracts. There were cytoplasmic changes in the ganglion cells of the anterior horns of the spinal cord. The examination showed the case to be one of organic, and not functional, disorder. It seemed safe to assume that the cause was not an infection, and the almost unavoidable conclusion was that the lesions were of toxic origin, possibly bacterial. The patient had been in the habit of taking headache powders, and it was possible that this was responsible for the cerebritis.

DR. J. ARTHUR BOOTH said he had seen this girl a few hours after her admission to the hospital, and had also been present at the autopsy. She was deeply comatose, and there was absolutely no previous history. The pupils were moderately dilated, and they reacted to light. There was absolutely no response to pin-pricks except in the feet and hands. He had been unable to make a diagnosis. At the autopsy, the brain appeared to him normal, except that it was rather soft.

DR. B. SACHS preferred to speak of this condition as a non-suppurative encephalitis. He had tried in a number of instances to recognize these cases and differentiate them from other cerebral conditions, particularly from apoplexy. He had however, found it extremely difficult to make the differential diagnosis. In children there was a special type in which the patient passed slowly into a state of unconsciousness, and remained there for some days or weeks, when consciousness was slowly regained. After this the most striking symptom was a persistent aphasia, though the general clinical picture was that of a cerebral hemiplegia.

DR. W. M. LESZYNSKY said that he had had an opportunity of examining this girl about one week before her death. At that time her condition was similar to that described by Dr. Booth. He learned that the rise of temperature had been coincident with the progress of the extensive sloughing bed-sore, and it was evident that the patient was then suffering from general sepsis. He was dis-

posed to think that this condition of general sepsis must have had considerable influence upon the post-mortem findings. He recalled a case in which a woman had remained unconscious for three months, requiring to be fed by the stomach tube during this time. Her condition was supposed to be due to ovarian trouble, and as at that time the fashion was to remove the ovaries for slight cause, both of her ovaries were removed without much benefit. She regained consciousness after the operation, and described her condition during the unconscious state. She died shortly afterward, and the postmortem findings failed to throw light upon the nature of the case.

DR. JOSEPH FRAENKEL said that the existence of non-purulent encephalitis had been proved in the monograph of Oppenheim. He would adopt Oppenheim's teaching with regard to these cases. The absence of the usual etiological factors, the presence of only very slight focal symptoms and the presence of fever should lead one to think of the existence of non-purulent encephalitis.

DR. JOSEPH COLLINS said that he was inclined to diagnose acute hemorrhagic nonpurulent encephalitis rather frequently — indeed, it was rare for a week to pass without this diagnosis being made. It did not seem to him that there was very great difficulty in making the diagnosis. For instance, a child of two and one-half years had been seen at his clinic that day. A short time ago it had become dull, inactive and irritable, and somewhat feverish. On the second day there was a convulsion lasting three quarters of an hour, most marked on the left side. After the child had remained stupid for ten or twelve days it gradually regained its normal activity. On examination, there was a condition of hemiparesis with normal mentality. This case seemed to him a very clear one of nonsuppurative encephalitis. In the class of cases referred to by Dr. Sachs he had never seen any rise of temperature, nor was there that degree of recovery which seemed to him so essential to justify the diagnosis of non-purulent encephalitis. He thought it was about as frequent as pneumonia, and the analogue of it. He had very grave doubt about the case reported by Dr. Brooks being one of nonsuppurative encephalitis. There must have been just as great changes in the spinal cord as in the brain, otherwise there would not have been such a rapid and extensive development of bed-sore. It was possible that there was present some intoxication that had not been revealed by the investigation, and which might explain the symptoms and the cause of death in some other way. The clinical description seemed to point to encephalomyelitis.

DR. R. H. CUNNINGHAM said that he had seen two somewhat similar cases. One of them was in Mount Sinai Hospital many years ago. The history was that the young woman after a disappointment in love had begun to be sleepy and stupid, and then became unconscious. Pin-pricks or faradic stimulation of the skin caused some response at first, but in a few days she became deeply comatose. The temperature was moderate for a few weeks, and then it suddenly rose and death soon ensued. The autopsy findings were negative. He had examined some sections of the brain and spinal cord, and had found leucocytes surrounding the blood vessels.

The Weigert method showed absolutely no change. The diagnosis at that time was subacute cerebritis. In 1895 he had seen a similar case, occurring in a school girl. The symptoms and course were about the same, but death occurred in about two weeks. The autopsy findings here also were negative. The microscopical examination of the brain gave exactly the same results. These findings were certainly not characteristic of any one disease.

DR. BROOKS said that undoubtedly the patient became septic from the large bed sore, but this was so shortly before death that the autopsy did not show the changes which were ordinarily observed in the organs under such conditions. On admission, the patient had fever, and the bed sore did not develop for a week or ten days afterward. If there were a septic condition arising from the bed sore there would have been a general infection of the blood, and various micro-organisms would have been found in the blood, yet a very competent bacteriologist failed to find any such condition. All of the classical stages of inflammation were represented in the brain. He had made careful sections of the cord, but had been unable to find the inflammatory process which one would naturally look for as the cause of the bed sore.

CASE OF MYOCLONUS MULTIPLEX, FRIEDREICH.

DR. J. RAMSEY HUNT reported a case of this kind that he had seen in July, 1901, together with the autopsy findings. The man was forty-five years of age, a tailor by occupation, and a man of good habits. A few months before admission to Bellevue Hospital one knee had been operated upon for tuberculosis. The peculiar tonic contractions of the muscles began some months previously. There was a history of despondency from financial straits. The muscles of the arms and legs, and of the shoulder girdle, showed very active twitchings. The whole muscle would bound forward as if by an electrical stimulation. No tetanic contraction was detected. The face muscles showed none of these contractions. The latter were most active when the patient was recumbent. The isolated contraction of individual muscles, such as the supinator longus and the sartorius, was the most noticeable feature. Sensation was undisturbed. The tendon and skin reflexes were very active. There were no stigmata of hysteria, and no evidences of mental impairment. A few weeks later he developed fever, and died apparently of general tuberculosis. The myoclonus persisted throughout the acute febrile attack, and for fifteen minutes or more after cardiac pulsations had ceased. A careful examination was made of the Rolandic and other areas of the cerebral cortex of the spinal cord at different levels by all of the usual methods, but with negative results. The affected muscles showed an unusually marked hypertrophy. The transverse striations were normal. In some places a central position of the nucleus of the sarcolemma sheath was noted.

CASE OF CHOREIC TIC, WITH REMARKS ON THE CLASSIFICATION OF MYOSPASMS.

DR. CHARLES L. DANA read this paper. He said that apparently no case had been observed in England, Scotland or Ireland, whereas fourteen

cases had been reported in this country, and two other cases had been reported under a different name. After carefully reading the descriptions he had come to the conclusion that no case of paramyoclonus of Friedreich had been reported in this country, not even the case just reported by Dr. Hunt, although it came nearer to that type than the others. The speaker then reported a case of paramyoclonus like those that had been published by other American observers. The patient was a man of forty-two with a history of the mother having had similar attacks during the time she was pregnant with this son. The man said he had been healthy until the age of eleven years, when he had been rendered unconscious by the kick of a horse. Shortly after this the first attack of myoclonus developed. The trouble continued with various remissions for the twenty-three years which had elapsed before coming under Dr. Dana's observation. When first seen he was nervous, anemic and badly nourished. There was no disorder of the sensory sphere. When the attacks came on he was seized with rhythmic movements of the head, and the hands and feet quivered. During the attack there was considerable palpitation of the heart; he perspired profusely and became exhausted. These contractions came on at very short intervals, and were apt to last for several days unless he took some narcotic, when the attack would cease. The patient had not been improved by any treatment he had employed, including hypnotism. A short time ago the patient reported that his general health was much better, and that the attacks were milder and less frequent. Myoclonus multiplex, Dr. Dana said, occurred also in connection with epilepsy. Mention was made of a case of myoclonus that had been under observation for a number of years. The attacks had developed after an operation on the thyroid gland following an abscess. The contractions were both clonic and tonic, and involved practically the whole musculature of the body. He looked upon the case as a mixture of chronic chorea and tic. Myoclonus occurred in association with epilepsy, chorea, tic and paresis; it also occurred in family forms. All these types of myoclonus were distinctly degenerative types of mobile spasm. There was another group of myoclonus multiplex which occurred in the form of recurrent spasmodic attacks, although sometimes the attacks were continuous. The trunk muscles and the proximal segments of the body were chiefly affected, and the contractions were very violent and of a rhythmic character. These cases had been called hysterical myoclonus, but in the cases he had seen there had been no distinct evidence of hysteria. Fright or shock was a common etiological factor; his own case was of the family type. The cases reported by American observers approached more closely to a disease entity than did the case of Friedreich. He was inclined to think that the case of Friedreich belonged more properly to the class designated as myokymia. There had been reported cases of paramyotonus which ran a course quite comparable with that of paramyoclonus.

DR. B. ONUF said that it was difficult to determine from the clinical reports found in the literature whether the muscles were hypertrophied or atro-

phied, and the subject was still further confused by the variations in the muscle fibers resulting from the use of various hardening fluids.

DR. L. PIERCE CLARK believed that Dr. Hunt's case was a typical one of myoclonus. It was very evident that others had not met with Friedreich's type. In some recent experiments the injection of carbolic acid into animals produced a condition of myoclonus multiplex. Recovery almost never took place in a well-marked case. The fact that over half of the cases reported had been associated with some form of disease, especially cortical, would seem to place the disease as cortical and not muscular. The treatment that he had found the most valuable consisted in the alternate use of bromides and chloral, with venesection and hyperdermoclysis or enteroclysis at the time of the attacks. In many respects the symptomatology of myoclonus simplex and status epilepticus was similar.

DR. HUNT said that the examination of many supposedly healthy muscle fibers had failed to reveal any like those in his case, the fibers in the latter being almost double the size of normal ones. It was not mentioned as an essential but as an interesting finding. In his opinion, the distinguishing feature of myoclonus of the Friedreich type was the occurrence of contractions of individual muscles not under the control of the will, except in conjunction with other muscles in the performance of co-ordinative acts.

DR. DANA said that it was evident that we were dealing with two very widely different diseases, one represented by the case reported by Dr. Hunt, and the other the myoclonus epilepticus described by Dr. Clark, and characterized by very violent contractions and co-ordinate movements. Dr. Clark had shown that the myoclonus of epilepsy was distinctly a cortical disease.

THE OBSTETRICAL SOCIETY OF BOSTON.

MALCOLM STORER, M.D., SECRETARY.

MEETING of Feb. 17, 1903. The President, DR. J. B. SWIFT, in the chair.

DR. W. L. BURRAGE reported,

A CASE OF UTERUS BICORNIS DUPLEX WITH DOUBLE CERVIX ABOVE, ONE OS, AND STRICTURE OF THE VAGINA,

(See page 442 of the Journal)

and showed specimens from the same removed by operation.

DR. C. H. HARE, by invitation, reported,

CASES OF DOUBLE UTERUS AND VAGINA.

(See page 441 of the Journal.)

DR. F. A. HIGGINS reported,

PREGNANCY IN A UTERUS BICORNIS SIMULATING EXTRA-UTERINE PREGNANCY.

(See page 443 of the Journal.)

DR. W. F. WHITNEY spoke at length on

MALFORMATIONS OF THE UTERUS.

DR. STORER: The case upon which Dr. Hare operated has been recently under my observation.

Since operation her condition has been vastly improved. Menstruation is practically painless, although coming every three weeks.

DR. CHARLES M. GREEN: I have seen but one such case, a uterus bicornis with complete septum. An interesting peculiarity was that she had gonorrhea in one uterus and vagina and not in the other.

DR. G. J. ENGELMANN: I once saw a case in consultation in which there was a pregnancy in each uterus, but they were of different ages. From one side there was a miscarriage at four months, while pregnancy went to term in the other side, and it was evident that the two conceptions were not simultaneous. I remember a peculiar case in the hands of a prominent surgeon, which occurred many years ago. A woman with the history of great pelvic suffering was operated upon. A supposed tumor was found and thought to be one of the ovary. It was removed and proved to be the smaller of two uteri.

DR. S. J. MIXTER: Once on being asked to curette a woman after a miscarriage, I found a double uterus, with the division at the cervix. I remember another case in which there was a distinct tumor to one side of the uterus, with signs of pregnancy and exquisite pain, — the typical history of extra-uterine pregnancy. I opened the abdomen and found an asymmetrical uterus. The diagnosis then lay between an interstitial pregnancy and a pregnancy in a bicornate uterus. It seemed to me best to leave it alone, even if it were an interstitial pregnancy, as I thought it was, and the result justified this, as she was finally delivered at term.

DR. CHARLES M. GREEN: I saw this case in consultation, and am firmly convinced that it was an interstitial pregnancy. Seeing her afterwards from time to time I had an excellent opportunity to watch the uterus become symmetrical.

DR. J. B. SWIFT: Besides the case reported by Dr. Burrage and one of Dr. Hare's I have seen one other case of double uterus, in which the diagnosis of pus tubes was made. The symptoms came on after a miscarriage. In the hospital, under ether, the peculiar feeling of the tumor made me suggest a double uterus. On opening the abdomen I found that to be the case, and the operation became merely an exploratory one. I would like to ask whether in these cases menstruation may not go on from each uterus, independent of the other.

DR. G. J. ENGELMANN: A case I observed many years ago with symptoms of congestion seemed to menstruate as if from one uterus. Both sides needed to be curetted, the only feature being that more menstrual fluid was discharged from one uterus than from the other.

DR. J. L. HILDRETH presented a paper entitled, RESULTS OF THE BACTERIOLOGICAL EXAMINATION OF COMMERCIAL SUTURE MATERIAL AND SPONGES.

In this paper it was shown that of a very large number of specimens of catgut, silk, tendon and sponges bought in the open market, by far the greater part presented evidences of bacterial contamination after a longer or shorter culture in bouillon. It was not claimed that these bacteria were necessarily of pathogenic nature, but it was insisted that such materials should be above suspicion.

DR. E. A. DARLING: It seems to me that the weak point in a study like this is that we do not know that these bacteria that render the test tubes cloudy do any harm. Many of them may be molds which we know are very difficult to destroy, and yet are harmless.

The tests that a bacteriologist employs in testing such material do not enable him to say that bacteriological sterility is the same as surgical sterility.

DR. F. B. MALLORY: We go through a series of tests like this once in three months or so at the City Hospital, testing practically everything in the surgical outfit. Of course we aim at surgical sterility.

DR. M. H. RICHARDSON: It seems to me that in investigating the sources of infection of wounds men are too prone to lay the blame on things that can be made absolutely sterile and think that they thereby excuse themselves. When it is possible to fulfil the requirements of absolute bacteriological sterility we should do it. But some things cannot be made absolutely sterile—the field of operation and the hands, for instance. Another thing of great importance that cannot be rendered sterile is the environment, that is, the atmosphere. Recently we have been in a period of great zymotic activity, and patients are just now especially susceptible to infection of every sort. Under such conditions it is not always fair to hold catgut, etc., to blame for accidents.

DR. F. B. HARRINGTON: For some time I have not used animal ligatures in any except septic cases. I like silk because it can be boiled practically indefinitely. I often boil it as much as thirty minutes. I agree with Dr. Richardson that atmospheric conditions are of importance. Any operation involves some infection, and the longer the operation lasts the greater is the chance of more infection than the body can resist. I think it is much harder to make sponges sterile than catgut. However, absolute sterility is not as necessary in sponges as in catgut, since sponges are not left inside the abdomen.

Recent Literature.

Vari Metodi Anestesi e Loro Indicazioni. Manuale teorico-pratico per medici e studenti. Dott. GIOVANNI PALLERONI, già 1° assistente alle Clinica Chirurgica Generale della R. Università di Palermo; Professore pareggiato di Patologia speciale chirurgica dimostrativa e propedeutica clinica chirurgica. Napoli, 1902.

The title-page of this manual is a good index of its contents. It begins with a rather full but well condensed history of anesthesia, which is followed by a short disquisition on the general action of anesthetics. Under each general anesthetic, Palleroni considers its purification, its physiological action, its elimination and the causes of death. Under each also, he considers the treatment of accidents, the technique of administration, and the indications and contraindications for the use of each one, chloroform, sulphuric ether and nitrous oxide, and the more uncommon ones, such as ethyl bromide, amylene, bromoform and the various A. C. E. mixtures.

Concerning general anesthesia by hypnosis, the author has little that is favorable to say, although he speaks of the practice of Luys, who for twenty minutes a day, during the seventh or eighth month of pregnancy, hypnotizes the patient and obtains an obstetric anesthesia, said to be effectual during labor.

Part II of the manual deals with local anesthesia, by compression, cocaine, liquid carbon dioxide, and the ethyl and methyl salts.

The third part is the portion of the work most interesting to American readers. Palleroni quotes freely from the works of Bier (*Deut. Zeits. f. Chir.*, 1899) and Tuffier (*Euvres, Med. Chir., de Critzmann*, n. 24, 1900, and *Comptes Rendues de la Soc. de Biol.*, 1900, p. 899). Concerning anesthesia induced by subarachnoid injection of cocaine, after reading the author's collection of subjective symptoms—vomiting three or four hours, headache up to eight days, chills, sweating, pallor, sighing respiration, and involuntary relaxation of sphincters—one is inclined to pause. F. Carini, who worked under Tramusti (*Polielinico*, 1900) found in animals the same changes in the cord following the temporary anemia which results from compression of the abdominal aorta that he found in cocainization under the membranes. Ossipon (*Deutsch. Zeits. f. Nerven*, Bd. XIX, 1901) found, experimentally, hyperemia of the meninges, punctiform hemorrhages, particularly of the gray substances of the cord, and apparent nutritive changes in the cells.

The technique of these injections and Tuffier's *résumé* of 252 operations by this method are reviewed at great length.

In conclusion, concerning general anesthesia, the author believes the best method for general surgery, obstetrics and eye work, to be by chloroform after a considerable dose of morphine; he believes that this form of narcosis is only rarely warrantable for diagnostic purposes and to be absolutely contraindicated in degenerations of the myocardium and in severe arterial atheroma. For dentistry he prefers local anesthesia, but favors nitrous oxide if a general anesthetic is needed.

For local anesthesia Palleroni stands for Kelene in most instances, and has many objections, which seem insufficient, to the method of Schleich. For spinal anesthesia by cocaine he seems to have a leaning, but wisely concludes that it is still too early to decide in its favor. In the conclusions, ether has no word of commendation.

A Course in Botany and Pharmacognosy. By HENRY KRAEMER, Ph.B., Ph.D., Professor of Botany and Pharmacognosy and Director of the Microscopical Laboratory in the Philadelphia College of Pharmacy. Illustrated with plates from original drawings by the author. Philadelphia: Henry Kraemer, Publisher. 1902.

This work hardly answers as a textbook of botany because the descriptions of plants are not complete enough and it is not classified in a manner facilitating the study of that subject. As a handbook of pharmacognosy, a subject dealing with the description of drugs used in medicine, with methods of recognition, it answers fairly well as far as crude organic drugs are concerned.

THE PANAMA CANAL, YELLOW FEVER AND ASIA.

THE experience of the past makes it plain that a change of trade routes brings with it a change in the distribution of many things besides the usual articles of commerce — such as products of the soil and manufactures. Among the most important problems connected with such changes in trade routes is the possible distribution or redistribution of flora and fauna, of diseases and especially of diseases belonging to the epidemic group. Nothing is more surely destructive of commerce than pestilence.

This is forcibly stated by Dr. Patrick Manson in a paper presented at a recent meeting (Feb. 25) of the Epidemiological Society of London. Dr. Manson is an ex-president of this society, and is at present medical adviser to the British Colonial Office. Dr. Manson's labors as an epidemiologist in China, and his discovery twenty-four years ago of the relation of the mosquito to filarial disease, are widely known and appreciated; when, therefore, he raises a warning voice on such a subject as the "Relation of the Panama Canal to the Introduction of Yellow Fever into Asia," he speaks as one having authority and on a subject whereof he knows.

There is no doubt but that our government is alive to the possibilities involved in this question and to the necessity of meeting them. But the question having much more than a national, having in fact an international, interest and importance, it is proper that it should meet with an international consideration. In fact, the questions raised are of direct and immediate moment. Apart from the opening of a Panama Canal, the establishment of direct steamship lines between ports in China and ports in Mexico precipitates the problem, although its solution, as far as our national responsibilities

are concerned, may still be delayed. Dr. Sambon informs us that the China Commercial Steamship Company has already inaugurated a regular monthly service between Hong Kong and Mexican ports. This service was to have begun March 1 last, and the steamers are designed to carry both passengers and freight.

As Dr. Manson points out, hitherto there has been no direct communication between the endemic haunts of yellow fever and Asia; hitherto the course of ships has been well to the north or well to the south of the tropic belt, and generally in cold or temperate zones, in temperatures inimical to yellow fever and the distributor of yellow fever — the *stegomyia fuscata*. Moreover, the time of transit will be reduced from about fifty days to three or four weeks, and the coaling stations en route will constitute convenient centers of distribution.

With its vast commercial interests in the tropical and subtropical Orient no nation is more, or even as much, concerned than is Great Britain in the proper and prompt solution of the problem of protecting Asia from yellow fever, and that problem apparently is already urgently demanding attention not because of a Panama Canal, but from the increasing trade of Mexico and the all-pervading British steamship. Fortunately, — and largely owing to the good work of Reed, Carroll, Agramonte, Guiteras, Gorgas, — sanitarians and epidemiologists are now in a position to grapple with this pressing problem with promise of success. Measures of quarantine at terminal ports will be given less or little attention; but the mosquito, if still allowed to exist at points of departure, will be made an unwelcome guest on shipboard and carefully secluded from water supplies.

Dr. Strong, director of the United States Biological Laboratory in Manila, and several members of the Epidemiological Society, emphasized the value of Dr. Manson's paper by an appreciative discussion. In his concluding paragraphs Dr. Manson pays such a generous tribute to American energy and enterprise that we permit ourselves the pleasure of reproducing them: "To have a thin red band across the Isthmus of Panama with the canal in the middle of it would gratify my patriotism. I am sorry the Panama Canal is not to be a British work. But I must confess that my regret is tempered by the knowledge that it is an American one; for I feel more confidence in American energy as regards sanitary matters than in our own. We are too slow, too timid, too niggardly, too much afraid of failure, too unbusinesslike. I like the prompt and autocratic way in which the great democracy deals with these things. America, ever since her

colonial expansion began, only a few years ago, whether in Honolulu, or in China, or in Manila, has shown an intelligence and practical appreciation of the benefits of medical and sanitary science, and an energy in these things to which we in England are not always accustomed. I cannot but feel, therefore, that in this matter of the Panama Canal the public interests are in the best hands. Still, this does not free us from our obligations to India, to Australia and the East generally; and I trust that this society will do something, by expressing its views freely, to strengthen the hands of government; or, if necessary, to stimulate our government to back up America in any measures that may be proposed or instituted with a view to keeping yellow fever out of Asia."

It so chanced that our readers are given this very week a letter from a most competent observer, which portrays in vivid colors the unhygienic condition obtaining at Canton and other Chinese cities, which is, in fact, characteristic of China; and our correspondent shows only too clearly what a field awaits the ravages of such a disease as yellow fever introduced *de novo* among such a population in tropical latitudes.

THE PROBLEM OF THE PREVENTION OF PUERPERAL SEPSIS.

The recent exploitation in the lay press of a supposedly new and wonderful cure for puerperal sepsis, which has generally been designated by the name of intravascular antiseptis, and the almost equally sudden and pronounced failure and abandonment of the cure, are perhaps sufficiently fresh in the minds of the medical public not to need special comment at the present time.

Such publications in the daily press are for obvious reasons generally to be deprecated. Yet looking at it from another standpoint, in the case of this particular disease the wide publication of the occurrence of every case of puerperal infection to the general as well as to the medical public might not in the end prove to be altogether an unmixed evil. It would at least serve to emphasize the fact that there is always more or less sepsis with us. We do not wish to be interpreted as advocating such measures as this would involve, but it does seem at times as if some such drastic means must be employed before so easily prevented a disease is to become less frequent.

The study of preventive medicine at the present time occupies a prominent place in the medical world. Large sums of money are annually spent, institutions are founded, and professorships and

fellowships are endowed for the furtherance of this object. Nevertheless, puerperal sepsis, which was perhaps the first to be recognized absolutely as a preventable disease, still continues to flourish in all communities and with considerable frequency. To what cause must this be attributed? The methods by which puerperal infections are to be avoided are readily formulated, and are easily learned and put in practice.

It is granted that occasionally a case of infection may arise as the result of a necessary break in the aseptic technique of delivery, when in the presence of a great emergency the medical attendant may suddenly be obliged to actively interfere. At such a time the immediate greater danger must take precedence over the more remote contingency of an infection. In the great majority of cases, however, infection must be due to one of two causes, either ignorance or wilful carelessness.

It is true that a few men still deny the existence of puerperal sepsis, while others deny that it may be avoided by the general practitioner under the ordinary precautions. Another class of practitioners refuse to accept the fact that the introduction of bacteria is an active agent in the production of the disease. Such men may be classed as hopeless, and will remain obdurate against any form of argument. We believe, however, that the great majority of cases occur through carelessness on the part of the medical attendant. Some cases undoubtedly arise from ignorance, which, with our present knowledge of the subject and the amount of literature which has been directed to it, can scarcely be said to be anything less than inexcusable. Repeated success with no bad results is unfortunately apt to beget over-confidence, and with it sometimes carelessness. In fact we have heard it stated by physicians, more or less in excuse for a case of sepsis, that having practised obstetrics for years without any bad results, they had become careless of their methods in delivery, and the natural results had sooner or later come. With these men the worry incident to even a moderate infection is usually a sufficient illustration of its dangers to lead them to correct bad habits. Nature is wonderfully kind in many instances to the parturient woman, but it is nevertheless true that eternal vigilance is the price of success in obstetrics, and every case should be treated on strictly surgical principles.

That puerperal sepsis is easily prevented is not difficult to prove to the ordinary mind. It is said that the statistics of lying-in hospitals are of no value for comparisons, because their patients are surrounded by safeguards which it is impossible to provide for the average patient in private practice.

This may be true of the in-patients, but it is far from true as it relates to the out-patients of a lying-in hospital in a large city. These patients, as a rule, are derived from the poorest classes in the community, to whom the supposed necessities for the conduct of an aseptic delivery, such as baths, clean clothing and fresh bed linen, are utter strangers. These patients are also attended by young doctors with very little or no experience in surgical or obstetric work. The results under these circumstances are marvelously good, and they so continue year after year in a very large number of cases. The accomplishment by these men of the prevention of infection, in so many cases, may be attributed almost wholly to the great emphasis which is laid in their obstetrical teaching upon the importance of the surgical cleanliness of the attendant, and, as far as possible, of the genitals of the patient. If such results can be obtained and maintained year after year by men of practically no experience, among surroundings of poverty and filth, there would seem to be very little reason why the practitioner of obstetrics, who is reasonably careful in his aseptic technique, should be troubled by cases of infection.

These statements will probably be accepted generally without serious question. Yet cases of puerperal sepsis are always present in considerable numbers, and the problem of prevention still remains unanswered. The medical public is ordinarily influenced and educated in two ways — first, by medical teaching, and, second, by medical literature. Obstetrical teaching, if it does anything, certainly emphasizes the importance of thorough surgical cleanliness in the conduct of confinement cases. Medical literature is constantly teeming with the subject of puerperal infections.

It seems to us that there are two other factors which must ultimately be of considerable influence in this direction. The first of these is the examination of young practitioners for the license to practice medicine. We believe that too much importance can scarcely be given to the subject of the prevention of puerperal infection by the State Board of Medical Registration, in the conduct of their examinations. This is certainly one of the most frequent and constant conditions that will ever confront us in the practice of medicine. The second factor, and we believe one that will ultimately be the most important in influencing against the careless practice of obstetrics, is public opinion. Already many people among the higher classes are beginning to realize that in a death from blood poisoning after confinement the question of personal responsibility is likely to arise. It is our belief that this tendency is sure to increase until it reaches such proportions

that no physician will be able to withstand its influence, unless he shall have surrounded his patient with every possible safeguard.

MEDICAL NOTES.

TYPHOID FEVER AT LELAND STANFORD UNIVERSITY. — It is reported that typhoid fever has appeared in epidemic form at the Leland Stanford University, in California. Upward of a hundred cases have already occurred.

COMMEMORATION OF REAPPEARANCE OF THE "INDEX MEDICUS." — Professors Osler and Welch of Baltimore gave a dinner at the Maryland Club April 18, to celebrate the reappearance of the *Index Medicus*. The editor, Dr. Robert Fletcher, was the guest of honor.

WOMEN PHYSICIANS IN RUSSIA. — Upwards of 100 women, out of about 850 candidates in medicine, have recently successfully passed the examinations permitting them to practice in Russia. It is stated that the women in general took a higher rank than the men. It is noteworthy that, in the various universities of Europe admitting women, a large proportion of Russians are usually in evidence.

A DEGREE FOR LORD LISTER. — It is reported that the honorary degree of doctor of science is to be conferred upon Lord Lister in June by the University of London.

APPROPRIATIONS FOR PHILADELPHIA HOSPITALS. — The Jefferson Medical College and Medico-Chirurgical hospitals have each received an appropriation of \$260,000 from the State for the purpose of erecting new buildings. The hospital of the University of Pennsylvania receives \$175,000 for maintenance and improvements, the latter including an x-ray building and outfit. — *Medical News*.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, April 22, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 22, scarlatina 30, typhoid fever 9, measles 34, smallpox 0.

NEW YORK.

APPROPRIATION FOR TUBERCULOSIS. — The Legislature has passed an appropriation of \$115,000 for the State Hospital for Tuberculosis in the Adirondacks.

DELEGATES TO THE MADRID CONGRESS. — The Medical Association of the Greater City of New York will send as delegates to the International

Medical Congress, at Madrid, its president, Dr. Andrew H. Smith (who as president also represents the New York Academy of Medicine), and Drs. Reginald H. Sayre, Ramon Guiteras, A. E. Macdonald, Davison H. Smith and W. Freudenthal.

Miscellany.

A TRIBUTE TO DR. T. GAILLARD THOMAS, NEW YORK.

AN admirable tribute to the late Dr. T. Gaillard Thomas was paid at the last meeting of the Medical Association of the Greater City of New York, of which he was one of the founders. The chairman of the committee having the matter in charge was Dr. Henry F. Walker, who was formerly associated with Dr. Thomas in practice. The following extracts from their report are of special interest:

"On graduation from the Charleston Medical College, in 1852, Dr. Thomas came to this city [New York] and entered, as interne, Bellevue Hospital. This was at a time when an epidemic of typhus fever was raging in the city, and the hospital wards were crowded with it. Several of the house staff had died from the disease, contracted in service, and it was to fill a vacancy made by such deaths that Dr. Thomas entered the hospital. This early action was typical of his whole career. He saw opportunity and he seized upon it. No man took tide at the flood more frequently than he. . . . Dr. Thomas made a success from the first. He had the cordial manner of his early Southern home, and he never lost it. He was of sanguine temperament, and that made him cheerful in the sick-room. His smile did as much good as his medicine. His personal confidence inspired trust, and his ready mind had a resource for every emergency. . . . He had the determination to teach. . . . As a lecturer, Dr. Thomas was most attractive. He had an animated and facile delivery and a keen discernment of the important point. This was forced home by change of phrase, iteration of idea without repetition, and by abundant illustration. He used the blackboard, picture, manikin—anything that would fix a thought in a pupil's memory. As a result, his rooms were always crowded. Students came, and graduates, who found there was always something to be learned. Dr. Thomas' didactic lectures were admirable, but his clinical lectures were better still. The very diversity of cases and the impossibility of preparation put him on his mettle and brought out his best efforts. . . . As a surgeon, he was confident in his diagnosis, deft with his hands, and quick in emergency. He was inventive, not only of instruments and appliances, but of methods. In obstetrics, in 1867, he suggested and used, in a family very near to him, the 'incubator' for an infant born at six and a quarter months, and the child lived to manhood. That apparatus, somewhat modified, is now part of the equipment of all lying-in hospitals. He waited for years to find an inverted uterus which he might operate on, if otherwise irreducible, by abdominal section and dilatation of the constricting ring. Everything comes to the man who waits,

and the case, at last found, was operated upon with immediate and permanent success. In gynecology he was first to remove a small ovarian tumor by cutting through the vagina instead of by abdominal section, a method now fully accepted. . . . Dr. Thomas was a favorite consultant. Other physicians valued his opinion and trusted his support. He was quick in observation, rapid in decision, firm, though not obstinate, in his opinion. He always had 'the courage of his convictions.' He was an honest man in every phase of his professional life; without disregard of his own rights, he recognized and respected the rights of others. He was a man of broad hospitality, kind, generous and helpful to younger men, a good adviser and a staunch friend. . . . Born at the South, and ardent in his sympathies, he accepted the arbitrament of war, and there was no more loyal citizen than he."

RITUAL CIRCUMCISION IN ITS OPERATIVE ASPECT.

CONSIDERABLE interest has recently been aroused both within the Jewish community and outside that body by the deaths of two infants shortly after the rite of circumcision, and under circumstances which left no doubt that in both cases death resulted directly from the operation. It appears, further, that in several other cases serious consequences have followed on circumcision, and it is stated that death after that operation has more than once come under the notice of the staff of the London Hospital. There can be little doubt that when the operation has been skillfully performed and the subsequent dressings carefully carried out, the mortality after infantile circumcision is extremely small. Indeed, until within the last few years deaths from this cause were so rare that many Jews were of opinion that it never occurred. Although this was at no time actually the fact, still such accidents were almost unknown. The increased frequency of misadventure during the last decade is chiefly, if not entirely, due to the Russian immigration, in consequence of which there is considerable overcrowding among the Jewish population of East London, so that the sanitary conditions are often far from satisfactory. Under these circumstances it is evident that evil results are likely to follow even the slightest operation unless this be performed with the greatest care and with the strictest aseptic precautions. The responsible heads of the Jewish community have always been alive to the necessity of taking means to secure that the rite of circumcision should be performed with due care, and for more than a century a charitable association with this object, known as the Initiation Society, has been in existence. In addition to receiving a money gift, every poor Jew applying to this society on the occasion of the circumcision of a child is provided, free of charge when necessary, with the services of a skilled circumcisor. Unfortunately the society has not found it possible to grant its license to circumcise only to qualified surgeons, but the candidate has always been called upon to satisfy the society's medical officer as to his skill after having received special instruction. It appears on inquiry that since the deaths referred to

above the Initiation Society has recast its rules, and it is now proposed to establish a medical board consisting entirely of registered surgeons to examine candidates and to compile a register of circumcisors approved after examination. Such circumcisors will be called upon, under pain of removal, to conform strictly to the rules laid down by the medical board, and these rules as drafted include every precaution which can be required to safeguard the child both during and after the operation. As far as the Initiation Society is concerned, the precautions proposed to be taken appear to be sufficient. The greatest difficulty will probably arise in dealing with those parents who from ignorance or obstinacy insist on having their children circumcised by operators other than those of the Society. However, when once the system is in full working order it will be less difficult to discourage unlicensed persons from operating. In cases where evil results follow the action of an unrecognized circumcisor the Society for the Prevention of Cruelty to Children might well be asked to take up the case, and it seems probable that the legal obligation on a parent to provide a proper operator for circumcision could be enforced in the same way as the obligation to call in a qualified practitioner when a child is ill. The dangers from circumcision should not be very serious, and considering the large number of Jewish children yearly submitted to the operation accidents are rare; but the matter calls for watchfulness on the part of the leaders of the Jewish community, and will no doubt receive from them the attention which it requires. — *British Medical Journal*.

MISUSE OF THE WORD LORGNETTE.

DR. WALTER L. PYLE contributes to *American Medicine* the following editorial comment on the misuse of the word lorgnette: With due deference to the authority of common usage, there seems good reason for believing that the ordinary interpretation of the word lorgnette, as used in American ophthalmic practice, is not correct. The word is derived from the French *lorgner*, to spy or peep; perhaps allied to *loren* of German dialect. In all the standard French dictionaries the word *lorgnette* is distinctly defined as an opera glass or a spyglass, while the word *lorgnon* is used to indicate an eyeglass or eyeglasses mounted on a handle, or to be more explicit, a quizzing glass. *Lorgnon à deux branches* is a double eyeglass. There is, however, the French term *lorgnette de spectacle*. Worcester defines lorgnette as an operaglass, giving Spiers as the authority. The last edition of Webster interprets lorgnette as an operaglass; *pl.* elaborate double eyeglasses. The Century dictionary defines lorgnette first as an operaglass, but gives a second definition as an equivalent to lorgnon. Lorgnon is described as an eyeglass or a pair of eyeglasses shutting into a frame, which, when in use, serves as a handle intended for examining objects at a little distance. This is a perfect description of the common American acceptance of the word lorgnette.

"She raises to her eyes of blue
Her lorgnon, as she looks at you."
— *The Atlantic*, lxiii, 649.

It is also stated in the Century that lorgnon is sometimes used synonymously with operaglass or lorgnette. The definitions of lorgnette in the Standard dictionary are: (1) A pair of eyeglasses carried on a long ornamental handle, into which glasses shut when not in use. (2) An operaglass, especially one with a long handle. Lorgnon is made synonymous with lorgnette and is also defined as a monocle.

Obituary.

WILLIAM SCOLLEY WHITWELL, M.D.

DR. WILLIAM SCOLLEY WHITWELL, whose death in New York occurred recently, was a Bostonian by association and parentage. His father was an engineer of distinction who lived in Boston the greater part of his life, and whose work, the large granite reservoir on Beacon Hill (removed a few years ago), was for a generation a testimonial of unusual professional skill and thoroughness.

Dr. Whitwell was born April 14, 1847, at Keene, N. H., while his father was living there in charge of the engineering work in that region.

Dr. Whitwell was educated in Boston schools, at the Phillips Exeter Academy, and at Harvard College, being graduated in 1869. He afterwards entered the Harvard Medical, and was graduated there, studying also in New York and at Vienna.

He served as a resident physician at the Charity Hospital, Blackwell's Island, New York, and as an assistant in Dr. Gray's asylum at Utica. Later he commenced practice in San Francisco, where for a time he was editor in charge of the leading medical journal of San Francisco. Subsequently he devoted especial attention to mental diseases, and established a private sanitarium in a suburb of San Francisco. A few years ago he moved to New York and practiced his specialty there until his death, having in connection with his city practice a sanitarium at Fishkill.

His death came unexpectedly, although his health has been somewhat impaired in the last two years.

Of an unusually attractive personality, he made warm friends among all who came in contact with him. All who knew him will always recall with pleasure his friendliness, geniality and the indefinable attraction which made his companionship something to be prized and not to be forgotten. He left a widow with three sons.

Correspondence.

MEDICAL IMPRESSIONS OF THE FAR EAST.

SPECIAL CORRESPONDENCE FROM CHINA AND JAPAN.

NATIVE LIFE IN HONGKONG AND CANTON AND OTHER CHINESE CITIES. — THE CHINESE UNASSIMILABLE AND UNABSORBABLE. — A MENACE TO HEALTH. — MEDICAL PRACTICE IN CHINA. — THE CONTRASTS OFFERED BY JAPAN.

MARCH, 1903.

MR. EDITOR: Hong Kong is, without doubt, the show city of Eastern Asia, and illustrates the admirable way with which the English administer their colonies. Of

course, in Hong Kong, they did not have the work of the past to undo, for the city is only some sixty years old, but the English are not deserving of any less credit for what they have accomplished. Hong Kong labors under the disadvantage of being built on the side of a mountain, but this very fact secures admirable drainage. The streets are broad and well paved, the houses are well constructed, and many of the large European buildings are magnificent. There is an efficient board of health, and the hospitals and other public institutions are admirable. The medical men are mostly English, and seem to represent a high type of professional excellence. The city is clean, well lighted and sewered, and is pervaded by a spirit of order and business enterprise. The great sanitary defect of Hong Kong is its water supply, which is not free from suspicion. It is understood that typhoid fever and dysentery are far too prevalent. Cholera does not exist, but plague cases are developing constantly in the Chinese section of the city. With the short distances intervening between Hong Kong and Macao, Canton, Amoy and other Chinese seaports, and the extensive trade carried on between them by Chinese junks, it would seem almost impossible for the former city to remain free from plague infection even should it become a clean port for a short period.

Unfortunately for the prospect of stamping out plague in the city, the lower class of Chinese in Hong Kong manifest strong opposition to the work of the Board of health with respect to the cleaning up and disinfecting of premises where plague has occurred. Plague cases are concealed by them as far as possible; and where detection is unavoidable, those attacked with plague are carried out into the streets under cover of darkness and left to die unattended, so that their associates may not be put to the discomforts attached to the cleaning up and disinfection of the houses in which the cases occurred. Much of the work of the Hong Kong Board of health is thus made of no avail through the impossibility of determining the premises in which plague cases develop and which are undoubtedly infected, and this kind of opposition is difficult to handle.

At present, plague exists in all the large seaport cities of China, such as Canton and Shanghai, and has apparently become an endemic disease there, liable to be carried at any time to uninfected ports. While of course there is no means of knowing how many Chinese are dying of plague in these cities, it is nevertheless certain that this number is large, though by no means as great as a couple of years ago, when hundreds and even thousands of Chinese died in a single day in Canton and their buried bodies lay in the streets of that city. The great difficulty of controlling plague even under relatively good sanitary conditions has been exemplified by the unavailing efforts of the health authorities of Singapore, Hong Kong, Manila and San Francisco, where, in spite of heroic measures, the disease still maintains a foothold; though the actual possibility of exterminating the infection has been demonstrated at much cost in Honolulu. When one realizes the persistency with which the plague infection, once established, manages to exist, and, knowing the conditions under which it flourishes, the visitor to a Chinese city marvels not at the number of its victims, but at the fact that any Chinamen at all are left alive. In the large Chinese cities every fundamental sanitary law — as to the necessity for plenty of sunlight and fresh air, the avoidance of overcrowding, a pure water supply, cleanliness of the surroundings, a proper disposal of the excreta, isolation of infectious disease, the disinfection of infectious matter — is totally disregarded.

In Canton, for instance, about four million people are packed together on a ground space which would be overcrowded with one fourth their number; this was probably primarily due to the desire to secure protection behind the old city walls, but is also a result of the instinctive racial desire of the Chinese to herd together. Throughout the entire city of Canton there is scarcely a bit of vacant ground. The houses are built as closely together as they can be packed. The main streets are never more than ten or twelve feet wide, the side streets are often so narrow as not to permit a sedan chair to pass, and the alleys so narrow that when two persons meet one must step into a doorway to let the other pass.

The houses are fortunately never more than two stories high, but to offset this advantage in regard to sunlight and air, the projecting eaves of the houses on both sides of the streets usually nearly, if not quite, touch each other. As the houses are several rooms deep, even the front rooms are almost like caves, gloomy even at mid-day. As is the case with many of the streets, sunlight never enters these houses. Foul air has little opportunity for escape — while the purifying influence of the winds can never make itself felt in the narrow, crooked streets. The soil is saturated with the organic filth of ages, while the roughly hewn slabs of stone with which many of the streets are paved, worn smooth by countless generations of naked feet, are slippery with foul-smelling slime. Sewerage or public water supply there is absolutely none. An open stone drain sometimes runs down the center of a larger street, loosely covered in by stone slabs; but as those drains seem to begin nowhere and end nowhere, and to have been constructed wholly without reference to fall, they serve simply to catch all liquid refuse and hold it in one vast stinking, putrid pool. As the houses have no drains, much of the liquid refuse is thrown into the streets, whence it runs through the crevices between the stone slabs into the drain beneath. Fortunately urine and feces have a steady commercial value as a fertilizer for the countless truck gardens around the city, so the excreta voided at home is preserved in the open buckets which are prominent articles of furniture in every Chinese house. The contents of these buckets are collected from time to time, and every ounce of it is carried out of the city in large tubs borne on the shoulders of Herculean coolies. With the crowded streets, accidents are not uncommon, and a part of the contents of these tubs is splashed out while being carried through the city. There are also many public sinks and urinals scattered at short intervals throughout the city. These are not as filthy as might be expected, as the urine and feces are being constantly removed by coolies. This frequent removal is not due at all to any sanitary reason, but because the Chinaman has found that as a result of putrefaction the excreta loses much of its qualities as a fertilizer — hence the contents of these public latrines are removed to the truck gardens with as little delay as possible. The urinals in these public latrines are merely open tubs — the closets consist of a rail behind which is a layer of wood or straw ashes, several inches thick, upon which the feces are passed. After a movement, an attendant sprinkles a little ashes — also a good fertilizer — over the fecal matter, and carefully removes it to a tub in which it is carried out of the city. It is said that the Chinamen caring for these latrines receive no pay, but secure quite an income from the sale of the excreta to gardeners. In addition to these public latrines, all the narrow alleys are used as urinals and frequently as closets by wayfarers. In view of the method of disposal and carriage of the excreta, it is no wonder that the city reeks with the foulest odors, which cling to the clothing and hair of the traveler for some time, in spite of airing and shampooing, and that the characteristic stench of a Chinese city has become proverbial. The odor of feces and putrid urine is everywhere.

Canton draws its water supply either from the filthy waters of the Pearl River, upon which about one million of the population are said to live in boats and into which they cast their excreta and refuse, or from shallow wells, the quality of the water in which is vile beyond description. Probably the greater part of the water supply is obtained from the latter source. Canton is built on low ground in which the level of the ground water is but six or eight feet below the surface. These wells are loosely walled with rough stones, possess no curb, and are located on any available piece of open ground. In many instances they are on the open street, perhaps in some blind corner, where they are not a yard away from the feet of hurrying thousands. Foul liquids from the open drains of the streets seep into them, storm waters flush the foul pavements into them during the rains, and dust blows into them when the weather is dry. There is no protection for them against pollution, and filth of such inexpressibly foul character is always so close to them that their contamination and infection cannot be avoided. Even the act of drawing the water contaminates the

well, for the coolie invariably sets his buckets into the slimy corruption on the pavement before lowering them and their adherent filth into the well. If the Chinese did not boil their drinking water in the preparation of tea, it would seem as if nothing could save the race from extermination. Of course, with no provision for the disposal of waste water, and with all the water used in a household carried by hand, often from long distances, proper bathing of the person and cleanliness of the clothing and surroundings are impossible. Hence all kinds of skin diseases are prevalent, and Chinese houses are dirty and foul smelling to the last degree.

As with water, food is contaminated by filthy habits of handling and by exposure to dust and flies. The fertilization of truck gardens with dilute human excreta makes the use of raw vegetables a highly dangerous matter. The Chinese, however, usually cook their food well in its preparation.

In their mode of life, the Chinese crowd together in a way which the American must see to understand. This they seem to do from choice as well as necessity. Twenty or thirty of them will crowd themselves at night into a filthy room, unlighted and unventilated, which with us would be regarded as close quarters even for a single white man. Tiers of bunks, each with only space to barely hold a recumbent Chinaman, rise to the ceiling and extend around the room, leaving a small passage in the center and cutting off all light and air.

In case of infectious disease occurring in a Chinese house, all the occupants are certain to be exposed to the infection. There is no attempt at isolation of the sick, nor are there usually facilities for carrying this out. Packed together in a small space, all are brought into close contact with the sick, and under conditions of lack of ventilation which favor the development of the disease in all those who are susceptible. The nature of the infectious matter is not understood, and no effort whatever is made for its disinfection. The operation of nature's disinfectants, sunlight, drying and fresh air, is carefully prevented by the Chinaman.

Under the conditions of life roughly outlined above, it is no wonder that plague has become endemic in the larger Chinese cities, and that nothing short of adverse meteorological changes or burning the cities to the ground will be able to destroy the plague infection. Smallpox and typhoid fever infection is everywhere; cholera makes periodic raids on these cities, but is unable, from climatic or telluric causes, to maintain a permanent foothold. So prevalent is disease and so unfavorable to life are the unsanitary conditions in Chinese cities that the sanitarian is forced to ask himself if the Chinese have not secured a higher resistance to infectious disease, as a result of their existence for hundreds of generations amid most unsanitary surroundings, than is the case with European peoples. It is true that the death-rate among the Chinese is high, especially the infant mortality, but life under the conditions which surround the Chinaman from his birth would mean almost the extermination of the white race. It is in China a case of the survival of the fittest; that is, the survival of those whose inherited immunity to infectious disease, transmitted from ancestors whose acquired immunity depended on an exceptionally high vital resistance, enables them to pass their lives under conditions to which the individual with a less power of resisting disease would succumb. An instance of the development of such immunity is seen in the case of the carnivora, who are relatively insusceptible to septic infection; in fighting over putrid carcasses these beasts of prey inflict wounds on each other which heal kindly, but which would mean death from septicemia to man or the herbivore. This is purely the result of the survival of the fittest; those susceptible to septic infection disappeared ages ago from the earth. The remainder have had their higher vital resistance fortified by an inherited immunity depending upon the septic inoculation of many generations of ancestors. May it not be some such influence as this which keeps the Chinaman hardy where other races succumb?

A visit to China also impresses another point upon the sanitarian. The Chinese are unassimilable and unabsorbable, retaining their customs and beliefs under all conditions and refusing to be influenced by modern ideas. Wherever they go they take the mode of life and habits

of China with them, and they will become a serious menace to the health of any community to which they may gain access in any numbers. They will treat all sanitary laws and regulations with indifference and passive resistance if not by open opposition, and they will create and keep alive centers of pestilence from which disease will spread from time to time to the surrounding population. We need look no further than San Francisco or Honolulu for an example of this fact.

Medical practice in China is of course most crude and empirical, as was to be expected in a country where there is no knowledge of anatomy, physiology, pathology or other branches of medical science. The Chinese physician's materia medica is most varied and extraordinary, and includes a large number of articles disgusting to civilized ideas. A common form of medical practice is based upon a chart of a human figure, ruled off into a dozen or so numbered squares. A medicine chest with correspondingly numbered jars of medicaments goes with this chart. Nothing could be simpler than the method of their use. If the patient complains of pain in the chest, the doctor looks over his chart, notes the number of the square over the affected region, and administers a dose from the jar having the same number, to the patient.

As illustrating the haphazard method of practicing medicine in China, mention may be made of a certain temple in Canton erected many hundred years ago to a Chinese physician, now worshiped as a god. This temple is largely resorted to by the sick in search of relief. On payment of the necessary fee to the priests, the sufferer is given a bamboo cylinder in which are about fifty flat strips of wood, all numbered. Standing before the image of the god, the afflicted individual recites his symptoms and prays for relief, at the same time shaking the cylinder until one of the strips of wood separates itself from the others and falls to the ground. This strip is then taken to the priest, who looks up the prescription entered in his book under the same number, together with the horoscope of the person securing this number. The patient can thus secure a sure cure for his disease or he can have his fortune told — if he will pay a double fee he can have them both.

In Japan the medical visitor finds sanitary and medical matters in refreshing contrast to those in China. A thoroughly modern quarantine service efficiently guards against the importation of disease from the plague spots of the Asian mainland, and uses in its work the latest scientific methods and appliances for diagnosis. Every quarantine launch carries its microscope and accessories for making diagnoses on the spot by bacteriological examination. The medical men are of a high order of intelligence and professional attainment, and such men as Kitasato stand among the world's leaders in scientific medicine. The Imperial University at Tokio has upwards of three thousand students, of whom five hundred are in the school of medicine. In size, equipment and methods of teaching the Tokio school ranks favorably with our schools of medicine in Chicago and other cities. The Japanese people are instinctively cleanly, and a daily hot bath is attained by even the poorest coolie. The acme of cleanliness as to garments, houses and surroundings is maintained, and plenty of sunlight, fresh air and space regarded as essential. There is none of the tendency to herd together, so characteristic of the Chinese. Earth or bucket closets are used for the excreta, and these are kept in the highest degree of sanitary neatness. Sewers are being installed in many places. The streets are wide and well paved, and are kept scrupulously clean by street scavengers. Much importance is placed upon the purity and sufficiency of the water supply. Food is handled in the most cleanly manner. Vegetables and fruits are scrubbed to the last degree of cleanliness and offered for sale in the most attractive way, decked with flowers and foliage. The people are happy and industrious, with a profound respect for law, order and official authority, submitting cheerfully to heavy taxation to improve their country and anxious to demonstrate the fitness of Japan to take its place among the best of the nations of the civilized world. Their charitable and medical institutions are admirable in their construction, equipment and administration, and

would be a credit to communities of equal size in the United States. The whole country is kept like a garden, and everything is cleanly, artistic, picturesque and pleasing to the eye. In fact no more dissimilar peoples, traits and conditions can be found than in China and Japan, and the medical man will be surprised at the high and low medical and sanitary extremes to be met with in those countries so close together.

"THE DOCTOR IN THE NAVY."

APRIL 17, 1903.

MR. EDITOR: In your issue of April 9, 1903, there is such an extraordinary and peculiar mass of misinformation under the caption "The Doctor in the Navy" that I feel obliged to enter a protest. Knowing your desire for accuracy, I hope you will correct some of the misstatements therein contained.

To begin with, we have the statement that in "Early times"—*antiquissimis temporibus*—the naval surgeon was "before the mast, with small pay and the privileges of an ordinary seaman." This is news to me, and while laying no claim to be an antiquarian, I feel quite certain that the naval surgeon was a commissioned officer in our service from its very beginning, and long before that time in other services. We get a very good idea of what the English naval surgeon was in the time of Smollett by reading his "Roderick Random." Smollett himself was a surgeon's mate, which corresponds pretty nearly with our present hospital steward. A surgeon's mate was not a commissioned officer, while the surgeon was. Yet the writer says that he was classed as "surgeon or surgeon's mate"—a distinction which is without a difference to him. Of course if we go back to medieval times, we find that all surgeons were barbers and bathers.

He proceeds: "At the present time in the navy he has no actual rank." This is not true. A medical officer has actual rank. But we can pass over many unimportant inaccuracies such as the statement that "examinations were formerly held at the Brooklyn Navy Yard," while, as a matter of fact, they were never held there, but at the Naval Hospital in Brooklyn.

We have a long description of the physical examination, which can be dismissed with the statement that the law requires that every candidate for the army or navy, no matter in what capacity he enters, must be sound in every respect. We learn that "the eyes also come in for a rigid but rather out-of-date form of examination." The method is nothing more than testing by Snellen's test types, which is used by oculists all over the world. This is the quickest and simplest test for acuity of vision. Where the necessity is apparent, this is followed by other methods of examination, even in the case of an enlisted man.

We can pass over many things until we are halted by the following remarkable sentences: "The results of the navy system have not as yet been in actual test, as every shore station has direct communication with large civil hospitals for consultation, and on sea-going ships they have a picked body of men under their observation. The war with Spain was not long enough to bring out the surgeon's value." The naval surgeon has had a pretty fair test in every war in which this country has been engaged—not to mention outside wars in which his services have been gratefully accepted by foreign governments. His reference to consultations with civil hospitals, I fail to understand. It is not a fact that every shore station has direct communication with civil hospitals; and military hospitals, whether army or navy, are no more apt to consult with civil hospitals than civil hospitals are apt to consult with each other. It is true that everybody on a ship is a picked man, but a picked man is as liable to injury and sickness as an "unpicked" man—from the exigencies of the service, often more so. The war with Spain was not long. But we can ask Cervera's men—many of them frightfully wounded—if it did not "bring out the navy surgeons' value."

Our writer then enters into the particulars of the sur-

geon's uniform with extreme minuteness. It seems to him to be a very important matter, but the surgeon of any length of service does not worry about such matters. He is mostly unconscious of the fact that he wears a uniform. After all the purpose of a uniform in any organized body of men is simply for identification. A naval officer wears a uniform for the same reason that a policeman or letter-carrier does—that he may be identified. But let it not be forgotten that the naval surgeon when operating wears the same uniform that Professor Lorenz does.

Our writer goes on to say: "The grade of surgeon is the last on which a regular physical and mental examination is required." This statement does not matter much, only it is not true. And so with most of the other information—it startles at first and then amuses.

We are gravely informed that "if the United States was to offer one half the entrance salary, they would have all the men they wanted and as competent surgeons." As a matter of fact there has been great difficulty in inducing competent and desirable young men to enter the service in view of its many hardships and deterrents. Under the present wise and energetic direction of Admiral Rixey, there is every prospect that the many vacancies now existing will be filled with the better class of medical graduates.

But of what use is it to contradict statement after statement—to say that there is no allowance for a ration at sea, etc.?

The writer speaks of an officer becoming surgeon-general through "influence." It is true that there is such a thing as influence in all walks of life, but there is far less of it in the navy than in a single civil hospital appointment with all its medical politics. After all this influence cannot be very pernicious when it permits such men as General Sternberg and Admiral Rixey to rise to the heads of their respective corps. President Roosevelt sent the nomination of the latter to the Senate with the significant words, "For eminent fitness." I hope it will rarely be the misfortune of the JOURNAL to publish an article on a subject of which the writer is so profoundly ignorant as in the present case.

A NAVAL SURGEON.

CONSERVATISM IN MASTOID OPERATIONS.

BOSTON, April 14, 1903.

MR. EDITOR: Wise and progressive aurists, especially those who have studied under Professor Politzer of Vienna, will rejoice as they read his latest edition of his "Ohrenheilkunde," a notice of the English translation of which, by Ballin and Heller, your JOURNAL published April 2.

The thoroughly conservative method of operating upon the mastoid had found advocates in this country long before Politzer wrote this edition of his handbook.

Few aurists in America appreciate the value of a thorough knowledge of pathology in undertaking this very radical procedure of opening the mastoid cells. If they were as carefully and thoroughly educated as Professor Politzer is, they might understand, as he unquestionably does, the intimate relationship existing between the various varieties of mastoid inflammation, with their etiology and their treatment.

It has been stated, and with truth, that "the occurrence of mastoid inflammation in cases under professional treatment is an indication of neglect." This should refer to all classes of cases. The acute very plainly, the chronic similarly.

Every earache case is readily amenable to treatment, and yields promptly to such when properly applied by the skillful and wise physician. In these days of destructive surgery it is encouraging to find honest teachers advocating constructive measures. It is far easier to tear down than to build up. It is also less difficult to prevent mastoid infection by having knowledge of its causation and applying suitable remedies than it is to remove it when well established. It is to be hoped that many more medical men will read Politzer.

Very truly yours,

EDMUND D. SPEAR, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, APRIL 11, 1903.

| CITIES. | Population Estimated, 1903. | Reported deaths in each. | Deaths under five years. | Percentage of deaths from | | | | | |

| Watertown . . . | 11,077 | 0 | — | — | — | — | — | — | |
| Plymouth . . . | 10,730 | — | — | — | — | — | — | — | |

Deaths reported, 3,499; under five years of age, 1,027; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 789, consumption 394, acute lung diseases 636, scarlet fever 46, whooping cough 38, cerebrospinal meningitis 8, smallpox 12, erysipelas 6, measles 33, typhoid fever 53, diarrheal diseases 85, diphtheria and croup 88.

From whooping cough, New York 5, Chicago 13, Philadelphia 7, Baltimore 2, Pittsburg 2, Providence 2, Boston 2, and Lynn, Lawrence, Quincy, Brookline and Melrose 1 each. From erysipelas, Chicago 1, Philadelphia 1, Boston 4. From smallpox, Chicago 3, Philadelphia 5, Baltimore 1, Pittsburg 3.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending March 28, the death-rate was 16.2. Deaths reported, 4,682; acute diseases of the respiratory organs (London) 250, whooping cough 121, diphtheria 68, measles 157, smallpox 13, scarlet fever 35.

The death-rate ranged from 6.3 in Handsworth, to 26.1 in Stockton-on-Tees; London 16.5, West Ham 13.7, Brighton 12.5, Portsmouth 16.3, Southampton 12.3, Plymouth 20.9, Bristol 13.5, Birmingham 16.6, Leicester 14.2, Nottingham 15.9, Bolton 12.9, Manchester 21.9, Salford 18.4, Bradford 17.8, Leeds 11.6, Hull 17.1, Newcastle-on-Tyne 15.3, Cardiff 16.0, Rhondda 16.1, Liverpool 19.3, Kings-Norton 10.6, Wigan 20.1.

METEOROLOGICAL RECORD.

For the week ending April 11, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

SOCIETY NOTICES.

THE AMERICAN GASTRO-ENTEROLOGICAL ASSOCIATION. — The sixth annual meeting of this association will be held at Washington, D. C., at the Stoneham, Thursday, May 14.

AMERICAN ACADEMY OF MEDICINE. — The twenty-eighth annual session of the American Academy of Medicine will be held at the "Arlington," Washington, D. C., on Monday and Tuesday, May 11 and 12, 1903.

AMERICAN GYNECOLOGICAL SOCIETY. — The twenty-eighth annual meeting of the American Gynecological Society will be held in Washington, D. C., May 12, 13 and 14, 1903. The sessions will be held in Lecture Hall No. 2, Medical Department Columbian University, No. 1325 H Street.

MEETING OF THE NATIONAL ASSOCIATION OF UNITED STATES PENSION EXAMINING SURGEONS. — On the 13th and 14th of May, 1903, the second annual meeting of the National Association of United States Pension Examining Surgeons will be held at Washington, D. C.

AMERICAN UROLOGICAL ASSOCIATION. — The second annual meeting of the American Urological Association will be held in the amphitheater of the New Orleans Polyclinic, May 8 and 9, 1903.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The annual meeting will be held at the Medical Library, 8 The Fenway, Saturday, April 25, 1903, at 8.15 P.M.

Papers: A Preliminary Report on Five Cases of Decapsulation of the Kidneys, Dr. J. B. Blake; The Blood in the Typhoid of Children, Dr. Frank S. Churchill of Chicago; The Formation of Loose Cartilages in the Knee Joint, Dr. E. A. Codman.

Business: Reports of Librarian and Treasurer, Election of Officers.

Supper after the meeting.

THOMAS MORGAN ROTCH,
President.

F. J. COTTON,
Secretary.

RECENT DEATHS.

DR. HOBART CHESMAN of New York, for many years a medical examiner for the Equitable Life Assurance Society, died in St. Luke's Hospital on April 11. He was born in the northern part of the State of New York, August 13, 1844, and was graduated from the medical department of the University of the City of New York in 1878. He served as interne at St. Luke's Hospital from 1878 to 1880.

CHARLES HOWE, M.D., M.M.S. S., died in Taunton, Feb. 12, 1903, aged eighty-two years.

BOOKS AND PAMPHLETS RECEIVED.

Cutaneous Blastomycosis. A Summary of the Observations of James Nevins Hyde, A.M., M.D., and Frank Hugh Montgomery, M.D. Reprint. Chicago, 1902.

To What Extent can General Practitioners Make Use of the Newer Diagnostic Methods? By Addison S. Thayer, M.D., of Portland, Me. Reprint. 1902.

Twenty-seventh Annual Report of the Managers and Officers of the New Jersey State Hospital at Morris Plains, for the year ending Oct. 31, 1902.

Address.

ADDRESS TO THE NURSES GRADUATING FROM THE FRAMINGHAM HOSPITAL IN 1902.

BY ARTHUR TRACY CABOT, A.M., M.D., BOSTON.

THIS is a significant occasion. I am sure that this audience will accept me as their spokesman when I say that we are here to show our appreciation of the good medical work that is going on in our Framingham Hospital; especially do we desire to give encouragement and evidence of our appreciation to these young women who have finished their formal studies there, and are now entering upon the wider field of study that the world opens before them.

Colleges have their commencements with much pomp and consequence, announcing to the world the entry into it of another company of learned men. This is your commencement, and in a quiet way you are celebrating here the graduation of another trained band of scholars.

All are familiar with the great advances in medical knowledge that have come in the past thirty years. Coincident with the advance in the knowledge of diseases that has been made in that time has come a very great advance also in the understanding of what proper medical care is, and how to obtain it for our patients. The treatment of patients based on more exact scientific understanding requires a scientific training in those who are to carry it out.

The professional nurse of fifty years ago was a careful, sympathetic attendant, often with a real genius for care of the sick, but without any training, except what she finally acquired by the practice of her calling. Nurses of that day varied so greatly in their qualifications that it was a common saying that nurses were born, not made." If one was not born a nurse she could never become a really good one. Now, we find that something more than natural aptitude is necessary. The nurse of the present day has become so indispensable an assistant to the physician; carries out so many important details of treatment; requires so much knowledge in order that her watchfulness may both safeguard the patient that she is attending and also protect the community from possible contagion from him, that a thorough scientific training is necessary to prepare her for her practice.

I well remember the earnest young women who made up the first class in the Training School of the Massachusetts General Hospital, and who were, therefore, the pioneers for our community in this sort of study. When they graduated, the physicians at once perceived that this training had indeed added greatly to their value.

As this became more and more understood, it was found that the large hospitals that first started training schools for nurses were inadequate to supply the demand, and the smaller hospitals throughout the Commonwealth were obliged to take up this duty in addition to their simpler requirement of caring for the sick.

Some years ago — not so many — I came down to this hospital of yours in Framingham to a housewarming. One of the other guests was a brother

surgeon from one of the small cities of the Commonwealth; a man who, although busy and driven with a large practice, still found time to devote a large measure of his indomitable energy to the problem of educating trained nurses. I refer to Dr. Alfred Worcester of Waltham. He was a pioneer in the establishment of small training schools for nurses.

He has shown how much may be accomplished in this way. Indeed, I am not sure that the small hospital is not better adapted to this work than the large institutions.

It has been found in medical education that much of the most valuable teaching must be done in small classes. Most of the manipulations and niceties of care that a nurse has to learn must be similarly taught to one or two at a time.

In a small hospital there is less rush and hurry than in a large one, and this quiet, persistent drill often receives more personal attention from the physician and head nurses than is possible in larger places, where they are constantly interrupted by other calls on their time. It is a mistake, therefore, to suppose that a crowded hospital is the best place to learn the nursing art.

One case well cared for gives a nurse more of the deft skill that makes things easy for the sick person than a dozen cases less perfectly attended to in the public wards of a great hospital.

I have had good reason to appreciate the value of nurses trained in many of these smaller schools, and remember with pleasure good services rendered me by graduates of this Framingham Hospital.

The advance in medicine is still going on, and the teaching of nurses must keep pace with this. Their training must be more thorough, and the range of subjects taught them must gradually become wider. At the same time, the public is coming to a greater and greater appreciation of the value of trained nursing. The demand is constantly increasing. This demand must be met, and in the future more nurses must be taught than in the past, and they must be taught more, and a large part of this added burden must fall on the small hospitals.

Fortunately, these smaller hospitals are growing in size and importance. They are becoming more and more able to do this added work, and they are making themselves more and more valuable to the neighborhoods that they are thus serving. It is well for the community that recognizes these services and gives to this largely gratuitous medical work the support that it so richly merits.

And now I wish to say a few words to the graduating class. Much might be said about the beauty of the profession you have chosen, and it is a delightful thing to feel your power to assuage suffering and to avert woe.

Your choice of a physician to address you to-day makes me feel sure that you wish to hear words practical rather than sentimental on this occasion. You are entering on a career which you can make an interesting calling, or an absorbing profession, according as you regard your studies as now finished, or as only just beginning. If you go forth in the community to practice the arts that you have been already taught, you will do great good, and be, no doubt, successful as the world measures success. If, however, you feel that what you have already learned is merely the beginning of life-long

endeavor to learn more, then you may rightly say that yours is indeed a learned profession. You will then enjoy all the delights that learning and investigation bring. You will be constantly moving forward, reaching new points of interest, and will be contributing to the general advance of medicine.

During your tutelage here you have learned many important facts and have had thorough training in the practical work of a nurse. Your studies in physiology and anatomy have informed you as to some of the functions of the body, and have prepared you for further study.

All of this knowledge is a valuable possession, but if your training has cultivated and established in you the habit of close, accurate observation, you have acquired something more important than all the rest. Your senses and perceptions will be then so sharpened by constant use that you will discover, as by an instinct, the wants and needs of your patients. Fleeting signs that would escape an unobservant person will serve as guides for you in your care of the sick person, and you will have acquired that great gift of trained sympathy or tact which knows when to interfere and when to let alone. Then will you have reached the summit of the nursing art. You will save the strength of the feeble and will give courage to those that are stronger than they think. In this way are many feet turned back from the brink of the grave.

To the physician too, the nurse's value depends largely upon her watchfulness. He is with his patient occasionally; the nurse is on the ground all of the time. She must serve, then, as eyes for the doctor, and he must learn many things about his patient from her observation and report. Every physician knows the comfort of feeling that the observation is correct and the report intelligent.

As I said in commencing, the nursing art has advanced with the advance in medicine. As I believe, this advance in medicine is but now commencing. I am of opinion that the training in nursing must be prepared for constant advance in the future. I believe that the two years usually given to the curriculum is already too short for a nurse of moderate capacity to acquire the knowledge and training that she really ought to have. It would be better for our hospitals to have the nurse stay for a longer course; changes would come less frequently, and they would get, during the third year, some of the fruits of the drill which they have put into the first two years of their training. It would, also, I am sure, be time well spent for the nurses. They would be far better equipped when they began their private work, and would easily show their superiority to those who had had a shorter training.

I should hope that in this longer course of study which I believe is coming in the near future, exercises would be devised which would train the nurse in making her own observations.

I well remember that when I began the study of natural history, Prof. Louis Agassiz put in my hand a dried coral, and told me to study it and learn about it from my own unaided observation all that I could. For many hours I sat turning this dried skeleton of a dead community over in my hand, and well remember the way in which its various characteristics gradually forced themselves upon my attention, and how the method of its

growth slowly unfolded itself before me. That was an invaluable lesson and one which every observer ought to learn for himself.

There are abundant opportunities in the wards of every hospital for giving this sort of training, and I think it should be given in the manner that I have described, by obliging the students to discover for themselves without help from their instructors. This sort of observation can and will be constantly exercised by you in your coming labor.

Do not tire of patient looking. You all have heard the old proverb and know why you have two eyes and only one tongue.

Use your eyes well first and only after thorough examination report what you have seen and ask, if you wish, its significance.

The nurse who does this will commend herself to patient and doctor; will find success, and will spread the fame of the school from which she came. This is the best return she can make for the debt she owes.

I thank you all for your kind attention to these few thoughts upon the higher education of women. It is a subject we are all interested in, and we wish these young women success in their chosen profession.

ALBUMOSURIA.¹

BY CHAUNCEY REA BURR, M.D. (HARV.); PH.B. (YALE),
PORTLAND, ME.

ALBUMOSURIA is the term used to describe that condition in which albumoses are present in the urine. It is a pathological state, and its importance has been but dimly appreciated till very recently. Together with albumosuria I shall also consider peptonuria, or the condition in which peptones are present in the urine. The line which divides the two is a very artificial one, and recent investigation has shown that many of the cases formerly described as peptonuria were, in reality, albumosuria, the real proteid present being deuteralbumose.

Albumoses are intermediate products in the digestion or hydration of proteids. There are four, to wit; proto-albumose, hetero-albumose, dys-albumose and deuteralbumose. The latter closely resembles peptone.

The passage from one to the other is effected by hydrolytic cleavage, that is, by the absorption of water. If deuteralbumose absorbs water it becomes peptone, and if peptone absorbs water it is split up into the waste products of digestion, leucin, tyrosin, etc.

Hydrolysis is effected through the agency of a proteolytic ferment, or enzyme. When occurring in the gastro-intestinal tract, these ferments are furnished by glands attendant thereto, as the gastric glands, the pancreas and the intestinal glands. The spleen and liver probably have proteolytic powers also. In addition to these, there are the ferments furnished by the bacteria contained in the ingested food and drink. The number of bacteria which have been found to flourish in the intestinal

¹ Read before the Portland Medical Club, Feb. 5, 1903.

contents is already large, and their ranks are constantly growing. Some fifty varieties have been described. A certain number are undoubtedly always present in health, while in disease, of course, the number may be considerably augmented. Some of these ferments form sugar from starch, some peptone from proteid, while others disintegrate fats. If for any reason these products are not absorbed, digestion or rather disintegration may be carried to its later results. The sugar becomes lactic acid and alcohol; the peptone is replaced by the amido-acids, leucin and tyrosin, by skatol, indol and phenol; the fats split up into valeric acid, butyric acid, etc. It is thus evident that the bacteria found in the chyme are a very considerable aid to digestion though by no means an essential to the process.

Peptone is the final product of proteid digestion, and as such is absorbed. But here a very remarkable fact comes into view. Peptones and albumoses are both found in the chyme, but neither occur in the normal blood. Their place in the latter is taken by serum albumin. No mechanical theory of absorption will account for this paradox. Peptones are diffusible and readily pass through animal membranes, and it is undoubtedly by virtue of this property that they are absorbed when and where they are. But the diffusion proceeds no farther. We are face to face with a vital process.

The peptones are absorbed by the epithelial cells which cover the intestinal villi and also probably by the leucocytes, which during digestion crowd the crypts and the submucous spaces. Within these cells (both leucocyte and epithelial) a reversible zymolysis or dehydration occurs, whereby the peptones are changed back again into albumin. The facts admit of no other interpretation. As to the details of the process, considerable light has been furnished recently by the work of physiologists. Jones and Hunt in Gould's "American Year Book of Medicine and Surgery for 1902," say: "The law that the continual removal of one of the products of a chemical reaction causes its continual formation was known to exist in the early part of the [nineteenth] century. Conversely the retarding action which is caused by the accumulation of the products of a chemical reaction is just as universally recognized. This law itself would furnish an explanation of the failure of enzymes to produce complete hydrolysis, but in several instances it has been experimentally shown that the decompositions produced under the influence of enzymes do reach completion when the products of the reaction are removed as they are formed.

"Hill,² however, gives an explanation of the law itself. He found that maltose not only decomposes into dextrose, but is capable also of forming a synthesis of maltose from dextrose. Thus whenever dextrose or maltose is submitted to the influence of the enzyme, the one is converted into the other till a certain condition of equilibrium has been established and no further decomposition follows. When, however, either one of these substances is removed, more of this must be formed at the expense of the other till equilibrium has again been established."

What Hill has shown to be true of maltose, Kastle

and Loewenhart³ have shown to be true of lipase (a new fat-splitting ferment). They not only decomposed ethyl-butyrate into its corresponding acid and alcohol, but out of these, by the aid of lipase, they reconstructed ethyl-butyrate.

The conditions for reversible zymolysis in the intestinal mucosa are very favorable. Peptones are continually being absorbed, and the equilibrium can only be restored by the reconversion of these into albumin. As this is removed by the portal circulation, more peptones are absorbed. Just where the change occurs, whether in the epithelial cell or the leucocyte, or in both, has not, as yet, been determined. But at all events I offer this suggestion of a reversible zymolysis in one or the other, as the explanation of an otherwise unexplainable phenomenon.

Albumoses, though present in the chyme, are never absorbed into the blood under normal conditions. This is doubtless due to the fact that they are not diffusible, that is, that they pass through animal membranes with difficulty, and very slowly.

This is all changed, however, when there is a break in the continuity of the intestinal mucosa. They are then absorbed into the blood with ease and reappear in the urine.

Chrostek and Stromayer⁴ administered to patients free from albuminuria, but in whom either gastric or intestinal ulceration was suspected, a mid-day meal of one or two ounces of peptone or somatose (which is a patented preparation of beef albumoses), mixed with water or broth. After two or three hours, the urine was examined for albumoses.

In six out of nine cases albumosuria was found to be present, and in every one of these tuberculous ulcers of the intestines were found at the necropsy.

On the other hand, a diet of albumoses administered to twenty healthy individuals failed to produce albumosuria in a single instance.

When once in the circulation, albumoses tend to remain there till further digested. They appear in the urine mostly as deutero-albumose and peptone. If proto-albumose or hetero-albumose are injected subcutaneously they are excreted as deutero-albumose; while if deutero-albumose is injected, it is excreted as peptone.

Albumosuria may appear independently of or in connection with albuminuria. In fact, the latter condition often masks the former.

The intestinal tract is not the only source whence albumoses are derived.

Gillespie⁵ believes that albumosuria is due to the excessive production and destruction of leucocytes.

Clinically, albumosuria is found where there is leucocytosis, and peptonuria where there is pus.

The leucocyte has a digestive ferment of its own, as shown by Rossbach and Leber, and is quite capable of producing albumoses, as in the case of a sterile abscess caused by hypodermic injections of croton oil, carbolic acid or ammonia water.

We also know that in the state in which leucocytosis occurs, there is nearly always a disturbance of the osmotic relations of the blood. The chlorides leave the serum for the cells, and the albumins and phosphates leave the cells for the serum. It is

² Am. Chem. Journ., xlix, p. 491.

³ Wien. klin. Woch., No. 47. 1896.

⁴ Lancet, July 6, 1897.

⁵ Journ. Am. Chem. Soc., lxxiii, p. 634.

highly probable, therefore, that a large part of the albumoses present in the blood of febrile cases are derived in this manner from the leucocytes.

Dead leucocytes are digested. This occurs in general where there is coagulation necrosis, and the process is greatly assisted by the ferments of the pyogenic bacteria which may happen to be present. Pus consists of serum albumin, albumoses, peptones, leucin, tyrosin, cholestrin, etc.

Fleischer found albumoses in the medulla of normal bone — the breeding-place of the polynuclear leucocyte.

Zuelger⁶ produced albumosuria in dogs by the administration of pyrocin. The albumosuria was soon obscured by albuminuria. There was also marked progressive anemia, and the bones were filled with lymphatic tissue.

DETECTION.

Clinically it is not necessary to distinguish between the different forms of albumoses present in the urine.

For their detection I prefer the methods given by Ogden,⁷ which are as follows:

(1) Take a small portion of urine in a test tube, and warm gently — a precipitate appears which is redissolved on boiling and reappears on cooling.

(2) Acidulate the urine with acetic acid, and add a few drops of a saturated solution of sodium chloride — a precipitate forms which disappears on heating and reappears on cooling.

(3) Add a few drops of nitric acid to the urine in a test tube. If the acid is not in excess a precipitate is formed which disappears on boiling and reappears on cooling.

(4) Add acetic acid, avoiding an excess, and then add a few drops of a solution of potassium ferrocyanide (1:10). A precipitate is formed which disappears on boiling and reappears on cooling.

(5) Completely saturate the urine at boiling point with neutral ammonium sulphate; filter and wash the precipitate with saturated solution of ammonium sulphate. Dissolve the precipitate in water or dilute sodium chloride solution and apply the beuret test. If albumoses are present a rose color results.

The beuret test is commonly applied in cases of peptonuria. It is unreliable because not only peptones, but albumoses and urobilin respond to it as well.

The only sure test is to proceed as in No. 5; that is, to saturate the urine (which should be acid in reaction) with ammonium sulphate, filter out the precipitate, and add to the filtrate either potassium mercuric iodide or picric acid. If a precipitate appears it is peptone.

PATHOLOGY.

Albumosuria occurs in a variety of conditions. Aldor⁸ found it present in almost 90% of febrile diseases. Krehl and Matthes⁹ found it of almost constant occurrence in both infectious and aseptic fevers. Other observers have found it in multiple myelosarcoma, osteomalacia, carcinoma, tertiary syphilis, hemiplegia, pneumonia, diphtheria, muscu-

lar atrophy and myxedema; it has also been found in leukemia and after prolonged exertion and in many other diseases. Peptonuria has been observed in suppurative diseases, as empyema, chronic bronchial catarrh and mixed tuberculosis, psoas abscess, purulent meningitis and acute articular rheumatism; it is also found in typhoid, typhus, variola, scarlet fever, mumps, erysipelas, carcinoma, catarrhal jaundice, apoplexy and pneumonia.

In nearly all of these diseases there is leucocytosis, and the degree of albumosuria (and peptonuria) may be expected to run parallel with this.

The pathology of the affection has not been exhausted when the diseases in which it occurs have been named. Albumoses are toxic, and the question may well be asked, and has been asked, whether the symptom complex to which the term "fever" is applied may not be due to albumose poisoning. Krehl and Matthes and Aldor¹⁰ are of the opinion that it is, and I am in thorough accord with them. Some of the deadliest toxins known are albumoses. Cobra venom consists of 98% of albumose and peptone and 2% of globulin. Its toxicity resides in the albumose.

The primary albumoses are more toxic than the secondary, and the peptones less toxic still. Pepsin itself is highly toxic.

Matthes showed that .07 gm. of deutero-albumose injected subcutaneously produced in healthy men a marked febrile reaction. In three cases of lupus there was also a decided local reaction exactly similar to that produced by tuberculin. Indeed, he considers tuberculin to be a mixture of deutero-albumose and peptone. As we approach the other end of the albumose scale the symptoms increase in severity. Thus injections of primary albumoses give rise not only to fever, but to hemorrhagic extravasations. The coagulability of the blood is lessened, secretion ceases and paralyses develop. There are neurotoxic and hemolytic principles in albumoses just as there are in serpent venoms. They unite with the neurons and the blood cells readily and rapidly, and cannot be removed therefrom by chemical reagents as can morphia or strychnia.

The higher centers of the brain and cord appear to be specifically affected, and in particular those of the medulla oblongata. Thus, in febrile diseases the tongue is generally coated and the fauces parched and dry. Deglutition is more or less painful and difficult, and there may be angina. The glosso-pharyngeal nerve supplies all these parts, and its origin is in the medulla oblongata. Its impaired function is the cause of these particular symptoms.

Again, the pneumogastric nerve has its origin in the medulla. Paresis of this causes pulmonary congestion and dyspnea, a rapid pulse, impaired motility of the stomach and dilatation, enlargement of the liver and spleen, and disordered digestion and absorption.

Space does not permit me to enlarge on the full pathology of albumose poisoning, but in general it is co-extensive with that of the septic state.

I wish, however, to add a few words as to the effect of albumoses on the blood. Most infectious diseases are accompanied by inflammatory leucocytosis. There is more or less anemia and a progress-

¹⁰ Op. cit.

ive loss of serum albumin. Coagulation may be increased or retarded, and appears to be dependent upon the amount of hemoglobin dissolved in the plasma. Degenerative changes in the erythrocytes, whatever their nature, are believed to result in a dissociation of the hemoglobin from the stroma of the latter.

The hemorrhagic extravasations and the lessened coagulability of the blood which occur in albumose poisoning are the direct effect of the hemolytic principle contained in the albumose. There is thus erythrolysis and possibly leucolysis. The anemia is thus accounted for.

The progressive loss of albumin is undoubtedly due to the increased metabolism of the body at large. The blood is drawn upon heavily for food.

As the blood becomes hydremic, which it does in most fevers, the isotonic tension between the blood cells and the serum is entirely upset.

This has been particularly investigated with regard to erythrocytes, but I doubt not applies equally well to most of the soft tissue body cells. To my mind it accounts for the emaciation which accompanies so many acute febrile diseases.

The osmotic law is that when two solutions of different concentration are separated by an animal membrane, the solutions pass through the membrane till the quantity of salt in each is equal.

In the case of erythrocytes, the chlorides pass from the serum to the cell, and the albumins and phosphates from the cell to the serum.

The disappearance of chlorides from fever urines is thus explained, as well as the increased output of nitrogenous waste products, sulphates and phosphates.

TREATMENT.

The treatment of albumosuria and peptonuria is, in general, that which is employed for the septic state. The most that we can do at present is to neutralize as far as possible the effects of the poison.

The neurotoxic element is best combated by oxygen and strychnia. Since albumoses form a chemical combination with the neurons, nothing short of an antitoxin will dislodge them. Antitoxins are cellular secretions. Such being the case, anything which increases cellular activity will, *ceteris paribus*, increase cellular secretion. Oxygen is one of these substances. The living body cell is aerobic. Again, oxygen assists in the digestion of proteids, and particularly in the disintegration of peptones. The excretion of urea is increased under its use, and it is therefore a diuretic. I have tried various methods of administering oxygen, but the one from which I have seen most benefit is by the ingestion of a new chemical compound, magnesium dioxide, called "Biogen" by its pharmaceutical sponsors. This preparation is claimed to contain 28% of oxygen.

Another agent of value is normal salt solution. It ought to be used much more frequently in septic states than is at present customary. It not only restores the isotonic tension of the blood where this has been disturbed and thereby prevents the drain of albumins and phosphates from the body cells, but is itself an antiseptic of no mean power. Solutions of sodium chloride are dissociated in the blood

into sodium and chlorine. The sodium unites with carbon dioxide to form sodium carbonate and bicarbonate, and the chlorine is left free to exert its antiseptic action.

The normal salt solution may be given hypodermically, but I prefer rectal injections of a pint or half a pint morning and night, the bowels having previously been emptied by an enema.

The circulation improves under its use, but it is well to remember that an excess produces dyspnea, headache, cardiac pain and even pulmonary edema.

Where albumosuria is the result of an intestinal lesion, this of course must be treated by itself, and the same is true of any local collection of pus.

In closing, I would again call attention to the clinical fact that apart from lesions of the digestive tract, albumosuria is indicative of leucocytosis, and peptonuria of pus absorption.

Treatment based upon these indications cannot go far astray.

A CASE OF JUVENILE AORTIC STENOSIS, WITH SUBSEQUENT INSUFFICIENCY. SUDDEN DEATH: AUTOPSY.

BY ALBERT N. BLODGETT, M.D., BOSTON.

THE subject of this paper was a man of twenty years, who had been under my observation for a period of about two and a half years. He had always been "well," according to his own statement, though he belonged to a family which adheres to a peculiar sect which does not acknowledge the existence of disease, but occasionally recognize a "claim" of pneumonia, rheumatism, etc., so that statements in relation to his former health may not have been wholly reliable. His father died after a long illness, with confinement to the bed, of what was called "curvature of the spine." The mother and one brother are in good health. The patient was about five feet eight inches in stature, and his weight varied slightly around 150 lbs. He had been much devoted to athletics, and was interested in anything which related to muscular exercise. He was fond of boxing in particular, and rode the bicycle with much enthusiasm. His face was partially covered with stains due to grains of powder. His nose was somewhat distorted from an accident, and his left arm was slightly deformed from a reputed fracture of the ulna; but this in no way interfered with its free use, or restrained him from any of his favorite exercises. He had no regular occupation, and passed his time mainly in the pursuit of pleasure, which generally took the form of active muscular sport. He had dissipated to some extent, and pointed with an evident sense of pride to a depressed cicatrix on the glans penis, as proof of his claim to be called a "sport." He gave a very unsatisfying account of this lesion and its behavior; no rational history of treatment or of subsequent developments, and during the period while under my observation there were no symptoms of specific character.

My attention was attracted to the patient by a casual examination of the pulse, which was 58 to 60, suddenly relaxing under the finger. It was fairly regular, but was accelerated by any excite-

ment or on moderate exertion. He stated that he could not run any distance, could not blow a cornet, on which he had become quite proficient, and that upon stooping he felt a pressure in the head, with shortness of breath. The complexion was rather dark at all times, so that any unusual afflux of blood to the skin was not very apparent; but the mucous membranes were the seat of more marked change in coloration. He was subject to a short and rather loose cough on exertion, unaccompanied by expectoration, and said that he "took cold" often during athletic exercise or other exertion, and he had frequent nosebleed, and was obliged to sleep on a high pillow; appetite and sleep were normal; all organic and voluntary functions otherwise in normal state; capillary pulse was not observed. He willingly consented to physical examination for purely scientific purposes, with the following results: Removal of his clothes revealed a most perfect muscular development, of which he was very proud. He might have served as a model for a Hercules. The several muscles were under unusual individual control, and he could contract independently many muscles not usually subject to voluntary control. The surface of the body resembled a superficial dissection. The several bodies of the recti abdominis were especially developed. The body was everywhere symmetrical except over the left cardiac area, where there was a slight prominence of the chest, extending from the third rib to the lower border of the sixth in the axillary line. Over this area could be felt a diffused heaving with a distinct and uniform thrill, coincident with the pulse at the wrist, and accompanied by a visible wave over the carotids, and seen also in the temporal arteries. There was also visible elevation in the epigastrium. The sensation to the hand over the precordium was that of painful effort, with tremulousness in the execution of function, such as is seen in forcible labor in a voluntary muscle.

Percussion revealed dullness over an area from the level of the seventh rib in the nipple line on the left to a line corresponding to the right border of the sternum, near ensiform cartilage, at the lower portion passing slightly beyond this bone; thence upward in a slightly curved line to about the union of the second costal cartilage with the rib; and from this point it passed inward and across the sternum at the second rib; thence descending in a large curve to the point first mentioned, thus including a roughly triangular space with its base across the lower part of the chest. The liver dullness was increased somewhat; that of the spleen normal.

Auscultation disclosed a loud, rough, systolic murmur, resembling the sound of a saw, occupying almost the whole of the enlarged heart area, and obscuring the other heart sounds to a marked degree. It was propagated into the axillæ, into the neck, and could be detected over the femoral artery. This murmur was systolic in time, of definite pitch, but hardly musical tone, and reached its greatest intensity over the second interspace of the right side, thus replacing wholly the normal first sound of the heart. The second sound was low in intensity, and followed so closely on the murmur that it could at times hardly be differentiated. There was also a faint murmur accompanying and following the closure of the aortic valves, indicating slight

incompetence, or at least this was suspected. No signs of insufficiency were detected over the seat of the mitral valve when the patient was quiet, but a slight murmur was heard in this region after exertion. This was thought to indicate a moderate regurgitation from distention of the left ventricle and stretching of the mitral orifice. The pulmonary second sound was intensified, and heard somewhat higher in the chest than its normal position. There were no friction or other abnormal sounds. No sphygmographic charts were taken. As the young man was not "sick," no treatment was prescribed; but he was earnestly advised to abstain from sudden or violent exertion, to drop tobacco and alcohol, and to refrain from harmful and vicious indulgences. (He stated that he knew his heart was affected, but would not promise to follow advice.)

The patient was examined about one year later, at which time he stated he was very well, except that he was easily "put out of breath." His resting pulse was 68, respiration was 24, color dusky, but he felt well otherwise. He had followed his ordinary mode of life without intermission, and freely indulged in athletics. Examination of the chest revealed the signs before observed, but in addition there was now a distinct and permanent murmur during diastole, heard loudest over the aortic area, the combination being that of a to-and-fro sawing murmur, of harsh character and without musical quality. The heart area was enlarged about 1 cm. above each of the former dimensions, and the chest was more prominent; he had also contracted a fresh gonorrhea, to which he gave little heed.

At the end of another year he was again examined with some care. His figure remained about the same, he kept up muscular exercises, principally boxing, and claimed to feel well, except from becoming more easily exhausted and "out of breath." His complexion was, however, quite dark, the mucous membranes were dusky, the conjunctivæ were slightly injected and of mildly cyanotic color. No capillary pulse detected. He stated that he had a persistent "cold" with a cough which he could not "shake," was obliged to sleep on a high pillow, and was "getting lazy." At this time a rough, harsh murmur could be easily heard through the patient's clothes at a distance from the chest. The pulse was sharp, quick, and its impulse was followed by sudden collapse of the vessel, the typical water-hammer pulse. In addition to what had formerly been found there was now no difficulty in detecting a murmur over the mitral area, and the pulmonic second sound was distinctly intensified. The liver dullness was increased, the spleen could be detected, and there seemed to be a slight amount of fluid in the abdominal cavity. There was also at this time a heaving pulsation at the top of the sternum, which had not been before present. The double aortic murmur was the same as at the last examination.

Six months later this young man fell dead while boxing with a college companion in a purely friendly encounter. He had received no severe blow, nor been in any way hard pressed; but fell after a moderate direct blow which landed on the side of the face. In his fall his body struck an earthen spittoon, which was broken, and from which several

slight cuts about the arms were received; otherwise no bodily injuries were found.

The body was at once taken in charge by the police and a judicial autopsy ordered, at which the writer was present. Rigor mortis was strongly marked; no appearances of cadaveric change were observed; no marks other than those noticed above were found. There was a pledget of cotton over the glans penis, which was soiled by secretion. The entire surface of the body and limbs was of a uniform dusky red color, so that the appearance resembled that of a red Indian. The face seemed turgid, but no ecchymosis was observed. The conjunctivae were injected and suffused.

The following notes of the autopsy, conducted by the medical examiner, were taken by Dr. Whitney, who has kindly allowed me to add them to the account of the clinical conditions reported above:

Jan. 27, 1903. *Autopsy* at 10.45 A.M., nineteen hours postmortem.

Body of a finely developed man, about twenty years of age, weighing 160 lbs., five feet nine inches in height. Rigor mortis everywhere present, and well marked. Extreme lividity of the dependent parts of the body. A slight recent bruise on the bridge of the nose, also an old white cicatrix quite indistinct on the left side of the nose. Over the left elbow was a somewhat jagged, incised wound about one-third inch in length by one-third inch in depth, quite recent, with blood on the adjacent skin. There were also two small abrasions of the skin over the ulnar side of the arm. There were no other external marks of injury. No edema of extremities.

Head.—The scalp was normal and there was no extravasation of blood or evidence of any injury.

Calvaria.—On cutting through the bone, very abundant, dark fluid blood poured out from the cut sinuses mixed with abundant cerebrospinal fluid. The bone was of normal thickness and appearance, and there was no fracture anywhere of the skull, nor hemorrhage between the dura and bone.

Dura mater and meninges.—Normal.

Brain.—Firm, vascular injection well marked, with a little clear fluid in the ventricles. Sections of the brain showed only the normal appearances everywhere. Pons, medulla oblongata and cerebellum, normal.

Vertebrae.—Normal.

Pericardium.—Normal glistening appearance except at one spot over the lower part of the left ventricle of the heart, where there was a fibrous thickening. The cavity contained a normal amount of fluid.

Heart.—Enlarged, especially on the left side; weighed 585 gm. It was firmly contracted, and contained but little blood in the ventricles, elsewhere the blood was dark and fluid. The left auricle was slightly hypertrophied, its walls measuring 2.75 cm. The mitral valve measured 8 cm., its curtains were normal. The aortic valves were sufficient to the water test, but although the free edges of the cusps were smooth, the orifice was greatly narrowed by partial fusion of the cusps, and by fibrous thickenings extending from the cusp to the surface of the aorta, which also prevented their free opening. This condition seemed to be an extension of a simi-

lar process which was on the surface of the aorta just above the valves, in the form of a slightly elevated, yellowish plate. The opening of the right coronary artery was somewhat contracted, the artery itself, with the exception of a very small, yellowish thickening in one part of its course, was normal. The opening of the left coronary artery was drawn out and valvelike in appearance, and suggested the possibility that it might not have freely admitted blood at all times; but the cut had passed in such a way that this could not be absolutely established. The papillary muscles showed a slight fibrous degeneration in places, as well as in the wall of the left ventricle, otherwise it was normal.

The walls and cavities of the right side of the heart presented nothing remarkable. The tricuspid valve measured 12 cm.

Pleura.—The diaphragm stood at the fourth interspace on the right side and at the fifth rib on the left. There were no adhesions and nothing abnormal in the cavities.

Lungs.—Rather voluminous, with abundant dark fluid blood, but everywhere crepitant. Trachea and bronchi injected; with no foreign substance anywhere.

Peritoneum.—Normal, everywhere smooth and glistening.

Stomach.—Contained a moderate amount of partly digested food, with chyme in the small intestine and rather soft feces in the large intestine.

Liver.—Of normal size, firm, of dark reddish-brown color and abundant blood, otherwise not remarkable.

Pancreas.—Of normal size, vessels injected, appearance normal.

Spleen.—Slightly enlarged, of a dark red color, follicles and trabeculae distinct.

Kidneys.—Of normal size, of a dark reddish blue color and abundant blood.

Bladder.—Empty and normal in appearance.

Testicles.—Normal.

DIAGNOSIS.

Chronic aortic endocarditis with stenosis of the opening.

Hypertrophy of the left heart.

General venous engorgement.

(Warren Museum, Specimen No. 9674, 22-2)

The clinical history of this case taken in connection with the results of my observation during many months, in which I had been able to detect the progressively increasing involvement of the structures at the aortic orifice, with the subsequent appearance of the signs of regurgitation, with its impending consequences, had led me to attribute the affection to the results of the syphilitic infection of some years before, the traces of which were still distinctly visible. There was no history of rheumatism or any other infective disorder to which the lesion of the heart could be ascribed, and it was most certainly not congenital. My reason for calling attention to these facts is that in conversation with Dr. Whitney he stated that he was disinclined to think syphilis the cause of the cardiac lesion. I hesitate to differ from the opinion of so accurate an observer and so experienced a pathologist as Dr.

Whitney, but I cannot free my mind from the conviction that the changes in the aorta, heart structure and valves in this case might have been due to the syphilitic infection. Since writing this paper, a short paragraph upon this topic has fallen under my eye in the *British Medical Journal*, which I have taken the liberty to abstract, and which applies very closely to the case here reported.

David Drummond,¹ in writing upon Cardiac Lesions, specially alludes as follows to "Syphilitic Heart": "The diagnosis of syphilitic disease of the heart is to be reckoned amongst the notable advances in clinical medicine of modern times. We now talk of a syphilitic heart as we do of a rheumatic heart or a kidney heart; and this, it need not be said, is important from a treatment point of view.

"It is true that so far attention has been limited to aortic lesions, and no doubt syphilis affects the aortic orifice much more frequently than the mitral; indeed with such frequency as to make up for the neglect of the latter.

"The absence of a rheumatic history in a case of cardiac disease in middle life will naturally suggest the cause next in order of frequency, which is probably syphilis, and this is of especial importance when a well-marked lesion exists. Aortic disease at this age has seldom existed from childhood, and therefore the patient is familiar with the history of its incidence if rheumatic; but it is not safe to attach too much importance to history, as a number of cases of aortic disease have come under observation with a rheumatic history, in which syphilis was recognized on the postmortem table. The patients are usually men between forty and fifty, the period of life when aneurism is common, and they generally complain of pain in the chest, which in some cases is felt on exertion and in others when at rest, though both varieties may occur in the same case. It is quite common for the patient's face to present the appearance of health, and, indeed, the pallor of aortic disease is seldom noticed till cardiac failure has set in. The murmur is usually double [too and fro], and well conducted into the vessels of the neck, which are generally dilated, and pulsation can be often felt in the episternal notch. This point forms one of the most characteristic signs, and when associated with pain and double aortic murmur in early middle life should always suggest syphilis as a cause.

"It is in syphilitic cases that the history of so-called 'ruptured valves' is to be met, as it is quite common for the statement to be made that the symptoms began suddenly. It is also common in this form of heart disease for compensation to fail whilst the patient is taking matters easily, indicating a progressive lesion. Sudden death is frequent, and particularly so when alcoholic excesses have been indulged in. If the case has been watched carefully during the earlier part of the history, when the lesion is confined to the aortic valves, it will be found that secondary mitral and tricuspid mischief very frequently show themselves by the development of systolic musical murmurs in their respective areas; this is of value as indicating that the lesion is primarily aortic and progressive. Careful examination will often lead to detection,

and in few cases of syphilitic disease of the heart recognized in the postmortem room is aortic dilatation absent."

MOUNTAIN SANATORIA FOR TUBERCULOSIS.

BY WALTER LINDLEY, M.D., LOS ANGELES, CAL.,

Professor of Gynecology, Medical College of the University of Southern California; Ex-President of the California State Medical Society.

"To the mountains for health" has been the cry from time immemorial. It was Celsus who in the 250th year of the Christian era wrote: "Soon as a man finds himself spitting and hacking on rising in the morning, he should immediately take possession of a cow, and go high up into the mountains and live on the fruit of that cow." While a large class of feeble patients may be better off in a low altitude and semi-tropical climate near the sea, yet there is no doubt but that the great mass of cases of tuberculosis, for whom there is yet hope, can find the surest avenue to health in the stimulating surroundings of the pine-clad mountains. The empirical idea of the ancients, in regard to the beneficial effects of the mountains, has been scientifically substantiated in our later days. Professor Roger of Paris, in his valuable work entitled, "An Introduction to Medicine," says when a person remains for some time in the mountains the blood is modified in three ways; namely, increased oxygen capacity, increase in number of red corpuscles, and increase in the iron content. Prof. Thomas J. Mays, in his work on the treatment of pulmonary consumption, says: "It is probably true that no other element in our environment has greater power of modifying bodily structure more palpably than mountain elevation. Its influence pertains especially to the respiratory organs, and is principally, if not entirely, exerted by the thinness or attenuation of the atmosphere, or by diminution of air pressure on the outside of the body. Protracted residence in an altitude of 6,000 feet increases the chest capacity to a marked extent. The therapeutic action of this altitude is that of a strong stimulant to the whole constitution, and especially to the nervous system. The air is cold, dry and attenuated, and is markedly invigorating."

In a recent work published in Mexico,¹ which won the Hodgkins Prize of the Smithsonian Institute, Herreta and Lope devote a chapter to the treatment of tuberculosis by altitude, noteworthy in many respects. They find that statistics show that not only in men, but in lower animals, tuberculosis is decreased in high regions. In 1885, out of 73,000 cattle killed in the general abattoir of the city of Mexico, only 45 were tuberculous. This favorable effect they attribute to the high solar illumination in high altitudes, and the dryness and coolness of the atmosphere as working against the existence of microbes. The benefits of rarefied air in consumption are given by the authors from their experimental and other observations as follows: "(1) Lessening pressure increases the circulation of air in the lungs, dilates them and obliges torpid parts to functionate. (2) Lessening pressure determines a greater quantity of blood in the lungs. (3) Lessening pressure permits a uniform distribution of

¹ Brit. Med. Journ., Nov. 1, 1902; p. 1418.

¹ La Vie sur les Hauts Plateaux.

blood, regulates its circulation and combats congestion. (4) Lessening pressure diminishes intrapulmonary tension in general, and particularly intervalvular tension. (5) Augmentation of red and white globules. (6) Desiccation of mucous surfaces; the favoring of evaporations. Besides experiments upon animals, observations of actual cases of tuberculosis, treated by rarefied air, are reported by the authors. Of thirteen patients thus treated, only one lost weight, one remained stationary, and eleven notably increased, one increasing 300 gm. in one day. In none, either healthy or tuberculous, were the alarming symptoms described by Paul Bert experienced."

The establishment of mountain sanatoria for health was first begun in the Alps, and the most popular place has been in the Davos Platz. This is an elevated valley about fourteen miles in length, and contains often as many as 10,000 people. The three miles of the valley in which the health resorts, Davos Platz and Dorfli, are located, has an altitude of 5,100 feet, and is surrounded by Alps ranging from 9,000 to 10,000 feet above sea level. St. Moritz is another noted resort, which lies in the Engadine over 6,000 feet above the level of the sea. The *Cyclopædia Britannica*, in describing this section, says they have nine months of winter and three months of cold weather. Another noted sanatorium is that of Arosa, which is reached from the railroad station of Chur by stage within five or six hours. The altitude here is 6,150 feet.

In our own country we have moderate altitude sanatoria in the mountains of the Carolinas, the Adirondack Cottage Sanitarium at an elevation of 1,500 feet, and the Loomis Sanitarium at an elevation of 2,200 feet, and several resorts in Colorado that have elevations of from 4,500 feet to 7,000 feet.

In the Alpine resorts the ground is uninterruptedly covered with snow for four months in the year, and the sun shines in the valley during the winter but five or six hours daily.

We have briefly related these facts in order to show faintly the great interest that is now being taken in the mountain treatment of tuberculosis.

There are several points that in an ideal mountain resort should be covered:

(1) An altitude of about 5,000 feet; (2) the greatest amount of sunshine; (3) the greatest possible number of days when outdoor exercise can be pleasantly taken; (4) purity of the atmosphere; (5) purity of the water supply; (6) pine forests for their balsamic effect on the atmosphere; (7) beauty of scenery, and inviting short tours.

A recent number of the *Brooklyn Medical Journal* in discussing this subject says: "Evidence is now accumulating that the mountain resorts are as beneficial in winter as in summer. Both the tendency to general hyperpyrexia and the local process are indications for the use of cold. So long as the body heat is not too much depressed — and that is easily within control — the inhalation of cold air is a positive advantage. The mountain air means, besides antipyresis, more oxygen per cubic inch, less moisture and sometimes the presence of ozone due to the friction of dry air upon the pine-clad hills."

It was with all this data, and much more that could be referred to, before us, that we felt the need in California of a mountain resort for tuberculosis

For the advanced cases, the hemorrhagic cases and the gouty cases of tuberculosis, the low altitude and marine resorts of Southern California already supplied ideal climate; but for the moderately advanced cases, and more hopeful cases, a mountain resort was needed, and after twenty-five years of personal investigation we finally chose the point where is now located the Idyllwild Sanatorium, in Strawberry Valley, San Jacinto Mountains, Riverside County. Why have we chosen this place? Because both winters and summers there are delightful. During the summer in the shade of the forest trees there is never an unpleasant day, while in the winter the sun shines almost every day; and, instead of six or eight hours of sunshine that can be had in the Alpine resorts, we have here long, sunny days throughout the winter. The fuhr, that annoying wind, that is so disagreeable in the Swiss Alps, is never experienced in these California mountains. While it is cold enough to be invigorating, and sometimes there are heavy snows, yet the coldest that has every been known was 13° F. above zero. This was one night in the winter of 1900. The next day was sunny and enjoyable. These mountains jut out into the Colorado desert, and during the night there is a pure air that comes in over this vast, arid plain, while on the west are seventy miles of fertile fields and orchards reaching to the Pacific Ocean; and during the day there is a refreshing ocean breeze. While immediately around the sanatorium the trees are sparse enough to admit abundance of sun, yet there are such extensive pine forests that the air is literally laden with balsamic fragrance.

There are many springs over this tract, and many springs through this valley, some of them sending forth quite large streams, and it is from one of these that the water is piped through all of the buildings, giving pure, soft drinking water that is cold enough for use even during midsummer.

This valley, which has an altitude ranging from 5,000 to 6,500 feet, is about six miles long and from one-half mile to a mile wide, and on each side of it the mountains range from 7,000 to 10,000 feet in height.

The government has recently established there a branch of the weather bureau, and from this time on accurate statistics will be available. This much is known — that the rainfall ranges from fifteen to twenty-five inches per annum.

As to the sanatorium itself, it consists of one fifty-room building, and of four cottages, two of which contain three rooms each, and two six rooms each. This building and the cottages are lighted by electricity, heated by steam, and furnished with liberal quota of private and public baths. There are also seven cottages for rent about one third of a mile away — these cottages also being lighted by electricity and fitted up for housekeeping. They all have bath tubs, and connected with the kitchen stove are boilers for furnishing hot water.

There is a store, dairy and meat market, from which the necessities and the comforts of life can be purchased for those who desire to live independently of the sanatorium.

At the sanatorium itself is a resident physician, and there are also trained nurses. The patients in the sanatorium have the attention of the doctor without extra charge.

There is also an excellent school for younger children, which has now been in successful session for three months. This gives an opportunity for educating the delicate children and the children of the delicate parents who may be in the sanatorium.

At present besides the numerous beautiful walks in the vicinity, there is a shooting range, golf links, lawn tennis, croquet, billiards and bowling alleys. Croquet is particularly suitable for the tuberculous; it is reasonably interesting, not so exciting as to lead to indiscretion, and gives a fair amount of exercise in the open.

As to the means of reaching the sanatorium it is one hundred miles east of Los Angeles, and the nearest railway station is Hemet. One takes the Santa Fé train at Los Angeles at 8.30 A.M., and reaches Hemet about 12 o'clock; after lunch one leaves Hemet by stage and arrives at Idyllwild at 5 P.M. The four and one-half hours' stage ride is picturesque and invigorating.

We have thus pointed out this new mountain resort, which from now on we believe will prove to be a great factor in contending with this disease. One other advantage is that if this location does not agree with a given patient it is so easy to change to a marine climate, or a low, equable, warm inland climate. Two hours will bring the patient from this altitude of a mile down into the midst of orange groves, and a short time longer will take the patient directly to the sea. It is also very accessible because the patient, or the resident physician, can consult with the patient's regular attendant at San Diego, San Francisco, Pasadena or Los Angeles in a few minutes by telephone.

The fact that we, who have resided in Southern California so many years, have finally taken up this enterprise is more convincing of our confidence as to its virtues than any amount of words, and we ask of the profession such co-operation as will make this new sanatorium of the greatest good to the greatest possible number.

New Instruments.

AN APPARATUS FOR ETHERIZING IN OPERATIONS ABOUT THE NOSE AND THROAT.¹

BY D. CROSBY GREENE, JR., M.D., BOSTON.

THE disadvantage of using a cone in etherizing for a prolonged operation about the nose or throat is that it necessitates frequent interruptions of the operation while the anesthetic is being administered.

The apparatus which I wish to demonstrate is one by which anesthesia is maintained by a stream of ether vapor, introduced into the mouth through a tube, while the operation is in progress.

A similar apparatus was described a year ago by Dr. H. P. Mosher of this city in the *BOSTON MEDICAL AND SURGICAL JOURNAL*.² His was a modification of one used for the last five years in cleft

palate operations by Dr. Fillebrown of the Harvard Dental School. Using this apparatus as a model, I have made some changes in the direction of simplicity and efficacy.

The object in view is to produce a strong stream of ether vapor which can at any moment be cut off, in whole or in part, at the will of the etherizer without wasting ether. Subjected to heat, ether becomes more volatile, and the vapor more anesthetic and less irritating to the mucous membrane of the air passages. The ether container is therefore placed in a warm-water jacket in a brass double cylinder. The object of having a double cylinder is to keep the ether at an approximately equable temperature of about 110° F. Water heated to this temperature is put into the inner cylinder and much hotter water (150° to 180° F.) into the large outer cylinder. In practice this

serves to keep the ether sufficiently warm for half or three quarters of an hour. In operations lasting longer than this it is advisable to replenish the hot water in the outer cylinder from time to time.

The glass ether container is connected with an air foot pump by a rubber tube, which at its middle expands into a dilatable rubber bag. A steady current of air is thus pumped into the ether chamber, becomes saturated with warm ether vapor, and escapes from the container through another tube which leads into the mouth of the patient.

The mouth tip is a bent hard rubber tube provided with an automatically closing stopcock, which is the distinctive feature of this apparatus.

¹ Read by invitation before the Eastern Section of the American Laryngological, Rhinological and Otolological Association, Boston, Feb. 14, 1903.

² *Boston Med. and Surg. Journ.*, Vol. cixvi, No. 4, pp. 84 and 85, Jan. 23, 1902.

By its use the etherizer is enabled to admit ether into the mouth during inspiration alone, thus avoiding waste of ether and sparing the operator the annoyance of having the strong vapor blown into his face during expiration. The ether can be kept under fairly high pressure from the foot pump and at the same time perfectly under the control of the etherizer.

In order to use the apparatus successfully, a fairly deep preliminary anesthesia with a cone is necessary. Otherwise there is likely to be considerable reflex cough and choking at the start, owing to the irritation of the strong ether vapor. In almost cases a satisfactory prolonged anesthesia can be obtained by using this apparatus alone, but in very difficult subjects it may be necessary at times to reapply the cone. When this has to be done, a rapid and deep anesthesia can be secured by connecting the mouth tip with a rubber breathing bag attached to a face piece which excludes air, the ether entering directly into the breathing bag and being inhaled thence through the face piece.

In brief, the procedure in managing a case with this apparatus is as follows: The patient is first deeply anesthetized, with gas and ether or ether alone, by the ordinary methods. Just before the cone is removed the apparatus is pumped up to a good pressure and the ether container placed in the warm-water jacket. As soon as the cone is removed, the mouth piece is inserted into the patient's mouth, which is kept open by a gag. The etherizer watches the respiration carefully and regulates the current of ether by the stopcock so that it is admitted into the patient's mouth during inspiration alone. In the case of an exceptionally difficult subject for ether anesthesia, it may become necessary to apply a cone in the manner I have described, but ordinarily the anesthesia runs smoothly for an indefinite length of time.

Clinical Department.

STRANGULATED HERNIA IN AN INFANT SIX WEEKS OLD—OPERATION—RECOVERY.¹

BY GEORGE TULLY VAUGHAN, M.D., WASHINGTON, D. C.

Assistant Surgeon General Marine Hospital Service, Washington, D. C.

STRANGULATED hernia in infants is probably more frequent than is generally supposed, the mother or nurse, no doubt, often attributing to colic the symptoms caused by hernia; yet the number of such cases reported is very small. Bull and Coley, with a very large experience, report only seven cases operated on under two years of age. The same authors report the youngest case operated on, according to Dowd's one hundred cases, as two months of age. The following case is of interest on account of its extreme youth:

E. L. F., colored male, aged forty-six days, was admitted to the Emergency Hospital, Jan. 8, 1903, with the diagnosis of strangulated hernia. The patient had been healthy until a few days before, when he was taken with a cough, and in the evening of Jan. 7 the mother noticed a swelling in the right

side of the scrotum and inguinal region, and between that time and the time of admission to hospital—twenty-four hours—the child seemed to be in pain, cried a great deal and vomited several times. On admission to hospital, at 6 P.M., a tight swelling about the size of a hen's egg was seen in the scrotum and inguinal region. It was without impulse on coughing and straining, and gentle taxis made no impression on it. The patient was anesthetized with chloroform and the intestine exposed by the usual incision—about eighteen inches of ileum being found in the sac of the tunica vaginalis testis, highly congested and a portion adherent to the bottom of the sac. This portion looked almost gangrenous in patches, and was observed for several minutes before deciding to restore it without resection. The constriction was at the internal ring, and this had to be slightly enlarged before the intestine could be reduced. The peritoneum and transversalis fascia were sewed across with kangaroo tendon as high up as possible, the cord was raised from its bed and one suture introduced to bring together the conjoined tendon and Poupart's ligament, the cord replaced, and the aponeurosis of the external oblique and fascia united over the cord by a continuous kangaroo tendon suture. The skin was united with continuous silkworm gut suture and sealed with collodion. No attempt was made to dissect the funicular process of the peritoneum from the cord—it was simply closed above by means of a kangaroo tendon suture carefully inserted so as not to injure the cord. Considerable difficulty was caused by the disproportion between the anatomy of the patient and the fingers of the surgeon.

There was no further trouble, no vomiting nor excessive crying. The stitches were removed on the 19th, eleven days after operation, and the patient was discharged well on the 24th.

Medical Progress.

PROGRESS IN THERAPEUTICS.

BY ELLIOTT P. JOSLIN, M.D., BOSTON.

(Concluded from No. 17, page 446.)

THEOCIN.⁶

THEOCIN (theophyllin) is a dimethyl xanthin. It was isolated from tea in 1888 by Kossel, but on account of its cost has never been used medicinally. In 1891 Traube succeeded in making it synthetically, and gave to it the name of theocin. Caffeine, a trimethyl xanthin, and theobromin, a dimethyl xanthin and isomer of theocin have long been known to have diuretic power, but theocin appears to be far more powerful than either.

Theocin is more readily soluble than theobromin, 1:179 parts instead of 1:1600 parts water. The toxicity corresponds to that of caffeine. Convulsions occur in cats with a dose of 0.1 gm. per kilo. body weight. On the heart and pulse, unlike caffeine, but similarly to theobromin, it exerts no action. It resembles caffeine in its exciting action on the nervous system.

¹ Read before the Fairfax County Medical Society, Feb. 5, 1903.

⁶ Die Therap. der Gegenwart, 1902, Nov., p. 490.

Dresler called attention to the diuretic action of theocin, which Ach some three years ago had also noted. Minkowski now has confirmed their statements, and reports his results with theocin in fourteen cases,—heart disease with passive congestion, nephritis, and a case of dropsy in consequence of a cardiac cirrhosis. The following case was the most remarkable: Man, thirty-five years old. Aortic insufficiency, with dilatation of the left ventricle. Large, hard liver. Albuminuria. Edema of the lower extremities. Quantity of urine at entrance 900 cm., but increased with digitalis to 1,300–1,700 cm., to fall later to 500–800 cm. The edema then increased and micturition was difficult on account of edema of the penis. On the 30th the quantity of urine was 820 cm. The digitalis was omitted, and the patient received 0.4 gm. (6 gr.) theocin, and in the next twenty-four hours the quantity of urine rose to 7,600 cm.! The following chart best shows the action of the drug.

In no other case was the diuresis as extensive, but it generally rose to 3,000–5,000 cm. when theocin was given. It was striking that theocin was found to act even where other diuretics had failed. The action of theocin is temporary, and it loses its efficiency when repeated. Nausea and anorexia may occur after its use. It does not disturb the sleep and exerts no deleterious influence upon the kidneys.

Schlesinger confirms the diuretic action of theocin claimed by Minkowski, having tested it in more than forty cases. These were chiefly cases of cardiac dropsy. Some of the patients had arterio-sclerosis or renal disease, and there were a few with inflammatory collections of fluid in the pleura or peritoneum. The diuretic action of theocin in cardiac cases was unquestioned. The quantity of urine increased in the first twenty-four hours, and the diuresis lasted for one to three days, and then

gradually subsided. The quantity of urine reached six liters in one case, and repeatedly was over three liters. Among these cases were those which had resisted all other internal medication.

Schlesinger also used theocin in renal cases—subacute Bright's and granular kidney with dropsy. The excretion of albumin was not unfavorably influenced.

The action of theocin in inflammatory affections of the pleura and peritoneum was far less favorable, and the same held true with two cases of hepatic cirrhosis with ascites.

The following observations are recorded: Theocin in 0.2-gm. (3-gr.) doses was prescribed for a patient with heart disease but normal kidneys, five times daily for two days. On the second day the patient was seized with convulsions, epileptic in character. The drug was continued, and the convulsions recurred on the next day. Theocin was then omitted, and during the several weeks which elapsed until the death of the patient no convulsions appeared. The convulsions lasted for several minutes, were accompanied by loss of consciousness, biting of the tongue and incontinence of urine and stools. An analogous case underwent the same experience after the use of only 0.2 gm. (3 gr.) theocin, repeated five times. The diuresis continued undiminished on the days of the convulsions.

Schlesinger considers the convulsions to be the direct result of the theocin, and adduces in confirmation the experimental evidence by which cramps were produced in cats by the administration of 0.1 gm. (1½ gr.) theocin per kilo body weight.

The diuretic action of theocin is so excellent that Schlesinger has combined with it, in order to lessen its exciting action, adonis vernalis. The bromides act unfavorably on the diuretic action, but adonis vernalis does not, but rather enhances it. Schlesinger omits the theocin as soon as headache or vomiting—signs of intoxication—appear. He gives the following formula:

| | | |
|-------------------------|-----|--------|
| Theocin, | 0.6 | (—1.0) |
| Infus. adonis vernalis, | 5 | 0 |
| Syrp. simplic., | 20 | 0 |
| Aqua, | 180 | 0 |

Sig. Take during twenty-four hours.

Using this prescription, he has met with no ill results in twenty cases, and recommends strongly its further use. Theocin is a powerful diuretic, but heroic remedy, and should be controlled by the simultaneous administration of adonis vernalis.

Meinertz⁸ confirms Minkowski's results, except that he has found theocin lost none of its power if repeated after intervals of a few days.

THE USE OF BORIC ACID AND BORAX AS A PRESERVATIVE.⁹

Oscar Liebreich comments on the law in Germany which prohibits the use of these materials as preservatives for meat, yet allows them in other foods. Their use is declared harmful to health in Germany, but in England no objection is raised against them. The laboratory belonging to the Imperial Health Department is occupied with work which aims to show by experiments on animals and

⁸ Therap. Monats. 1903, February. p. 58.

⁹ Therap. Monats. 1903, Feb. p. 36.

man the injurious effects of these preparations. Scientifically these experiments do not prove their point. More experiments are to follow. [The scientific zeal and the desire for the protection of the public health which our German friends manifest is interesting.]

PRURITUS.

The article of Robin and Dalche on the "Treatment of Vulvar Pruritus" is summarized in *American Medicine* for April 11, 1903. "Among the means employed are prolonged hot applications of 1:1000 solutions of corrosive sublimate, 10% solutions of chloral hydrate and 5% to 10% solutions of cocain. The following powder may be applied locally:

| | |
|---------------------|-----|
| Powdered orthoform. | |
| " diiodoform. | — |
| " tale, | aa. |

"The anesthesia produced by orthoform lasts longer than that by cocain. The following ointment may also be used:

| | |
|-----------------|----------------------------------|
| Menthol | 0.05 gm. ($\frac{1}{4}$ gr.) |
| Guaiacol | 0.3 gm. ($\frac{1}{2}$ –15 gr.) |
| Zinc oxid | 10.0 gm. (2½ dr.) |
| Vaseline | 30.0 gm. (1 oz.) |

"Ichthol may be used in 10% aqueous solution or in an ointment containing 15%. Ruge of Berlin washes the parts with soap, then with a solution of corrosive sublimate, followed by an application of 3% or 5% carbolized vaseline. Leredde uses a 5% ointment of methyl salicylate. When there is dyspepsia with fermentation, Robin prescribes erythrol with calcium fluorid as follows:

| | |
|-------------------------|--|
| Erythrol | 0.02 to 0.1 gm. ($\frac{1}{2}$ –1½ gr.) |
| Calcium fluorid | 0.02 to 0.1 gm. ($\frac{1}{2}$ –1½ gr.) |
| Calcined magnesia | 0.1 gm. (1½ gr.) |

"For one cachet. One cachet at the end of each meal. Erythrol is particularly indicated in butyric acid fermentation; if lactic acid fermentation is present, ammonium fluorid should be substituted, as follows:

| | |
|--------------------|----------------------------|
| Ammonium fluorid.. | 0.1 to 1.0 gm. (1½–15 gr.) |
| Water | 300. cc. (10 oz.) |

"One dessertspoonful during the two chief meals."

TREATMENT OF RECURRENT VOMITING IN CHILDREN.¹⁰

Edsall concludes that in one case, which he describes, the symptoms were due to an acid intoxication similar to the type seen in diabetes. Treatment directed toward this acid intoxication was successful. The child in question exhibited soon after vomiting a very marked odor of acetone. Twenty grains of bicarbonate of soda were ordered to be given every two hours. The child retained this perfectly, and after four or five doses the vomiting and nausea stopped. Another child, accustomed to attacks of vomiting a week in duration, under the alkaline treatment, was relieved of an attack in two days and a half. Three other similar cases were reported.

¹⁰Amer. Journ. of Med. Sci. 1903, April. p. 629.

VERONAL.¹¹

Veronal is a crystalline colorless body which melts at 191° C., tastes mildly bitter, is soluble in about 12 parts boiling water and in 115 parts water at 20° C. The chemical name is diethyl-acetyl urea.

The ordinary dose for sleeplessness is 0.5 gm. ($\frac{7}{16}$ gr.), which can at will be increased to 1 gm. (15 gr.). In weak patients 0.3 gm. ($\frac{1}{2}$ gr.) may suffice. If the veronal is given in solution, effect occurs in half an hour. It is best administered dissolved in a cup of warm tea, though it may be given as a powder. The authors have observed no untoward accompanying symptoms.

Emil Fischer and J. v. Mering have studied the chemical constitution and pharmacological action of the synthetic hypnotics now commonly used. Of these, chloral hydrate ($\text{CCl}_3\text{CH}(\text{OH})_2$) and its derivative, chloralamid ($\text{CCl}_2\text{CHOH} - \text{NHCHO}$), and in all probability paraldehyde ($\text{C}_6\text{H}_{12}\text{O}_3$), form

one class; amylene-hydrate $\left(\begin{array}{c} \text{CH}_3 \\ \text{CH}_3 > \text{C} - \text{OH} \\ \text{C}_2\text{H}_5 \end{array} \right)$

forms a second, and its action appears dependent upon, besides the alcohol group, the carbohy-drate atom, which is bound to three alkyl groups. Dormiol comes between these two classes, because it is a mixture of chloral and amylene-hydrate. Urethan ($\text{CO}(\text{NH}_2)(\text{OC}_2\text{H}_5)$), and its derivative, hedonal, form the third class. The fourth class is

represented by trional $\left[\begin{array}{c} \text{CH}_3 \\ \text{C}_2\text{H}_5 > \text{C} < \text{SO}_2\text{C}_2\text{H}_5 \end{array} \right)$

with its sulphur group. This is similar to amylene-hydrate, because of the carbon atom forming the center of the molecule, and being connected with two alkyl groups, and again by the presence of an ethyl group in each. With this in mind, they studied other compounds which contained a carbon atom united with several ethyl groups. The one which showed the greatest hypnotic power they named veronal.

Reports of Societies.

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

STATED meeting, April 13, 1903. The Vice-President, RANSFORD E. VAN GIESON, M.D., in the chair.

DR. SAMUEL G. GAUT read a paper on

THE NON-MEDICINAL TREATMENT OF CONSTIPATION.

The successful treatment of chronic constipation, he said, still remains a difficult problem. In many instances the failure to obtain good results is due to the fact that the physician, in his desire for prompt effects, is apt to over-drug the patient, instead of adopting more rational methods, which, while perhaps less satisfactory in the beginning, will eventually accomplish a permanent cure. A

¹¹Die Therap. der Gegenw. 1903, March. p. 97.

large number of cases are due to irregular habits, improper diet, lack of intestinal tonicities and secretion, or insufficient exercise, and must be treated by remedying such of these factors as are present. In another class of cases the trouble is dependent on abdominal or diseased conditions of the lower bowel, which require operation or local treatment.

In 1891 Dr. Gaut reported before the Kansas City Academy of Medicine a number of cases cured by the non-medicinal method, and since then he has treated by this several hundred cases, the majority of whom were permanently cured, while the remainder, with but few exceptions, were relieved to a greater or less degree. The principal features of the treatment practiced by him consist of the proper education of the patient, together with the administration of enemata when necessary, massage, electricity, divulsion or division of the sphincter muscle, and valvotomy, any or all of these being carried out as the case demands. Persistence in the treatment is an essential requisite for success. Regularity in the manner of living must be insisted on. The patient should abstain from foods which disagree with him or tend to clog the bowel, and laxative fruits, to be eaten preferably in the morning or at bed-time, should be included in his dietary. Two or three glasses of water taken on rising constitute an excellent laxative, and the free drinking of water throughout the day is of service in softening the feces and stimulating intestinal peristalsis. Those engaged in sedentary occupations should take plenty of systematic indoor or outdoor exercise. In the numerous cases in which the constipation is complicated with auto-intoxication, a morning cold bath, followed by a salt rub or vigorous friction of the skin with a Turkish towel, is of much service in promoting elimination. A systematic effort (to which sufficient time must be devoted) to evacuate the bowels should be made at a given hour daily.

Dr. Gaut regards the regular daily use of enemata as a most pernicious practice. In some instances, however, rectal or colonic injections are advisable early in the treatment, in order to secure necessary evacuations and prevent fecal impaction. Massage is an essential feature of the treatment. In addition to kneading the larger intestine, special massage is given over the liver and small intestine and locally to the rectum. The table on which the patient is placed is so arranged that the head may be raised or lowered and the body rotated from side to side, so that the intestines may be changed from one position to another. With the palm of the hand and ball of the thumb the operator makes firm but gentle pressure over the large intestine, beginning in the right iliac fossa and following the course of the colon over to the left; accompanying the pressure by thorough kneading of the parts with the fingers. These manipulations are repeated several times at each *séance*, and the treatment should occupy ten or twelve minutes. It is practiced every day at first and later twice a week. If unable to pay for the services of a masseur, the patient may receive much benefit from daily rolling, while lying in a recumbent position, a cloth-covered metal or bowling ball over the course of the colon.

In combination with other measures he has found electricity of value in many instances. The positive

electrode is placed over the spine or in the rectum or sigmoid colon, while the negative is moved about the abdomen over the region of the liver, the small intestine and the colon. As, in his opinion, hypertrophy or irritability of the sphincter muscle is an important factor in the etiology of constipation, its divulsion or division is frequently indicated. Gradual divulsion may be accomplished by the introduction of one, two and then three fingers, until the muscle has become sufficiently relaxed, or by the use of the Kelly or Pratt anal dilators or of Wale's graduated rubber bougies. Forceful or rapid divulsion, for which general anesthesia is required, is accomplished by stretching the muscle in every direction by means of the thumbs. In cases in which the sphincter is so thick and rigid that sufficient relaxation cannot be obtained by divulsion, division is necessary. After the injection of a 3% solution of beta-eucaine into the section of the sphincter to be incised, a bistoury, guided by the finger, is introduced well above the muscle and then withdrawn; in this way all the fibers are completely divided laterally or in the posterior median line. The after-treatment is the same as that for cutting operations for fistula.

When one or more of Houston's valves have become so hypertrophied as to obstruct the descent of feces, as is occasionally found to be the case, valvotomy is indicated. Martin was the first to suggest division of the thickened valves for the relief of constipation. After describing his operation Dr. Gaut stated that it was open to serious objections. Among these are its difficulty of performance, the considerable time required, the danger of hemorrhage, infection and peritonitis, the great pain due to the presence of the tampon left in the rectum, the confinement of the patient in bed for a week or more and the fact that no part of the obstructing valve is removed. As a substitute for the Martin operation Pennington suggested a clip for the purpose of dividing the valves by pressure-necrosis. With this idea in mind, Dr. Gaut has devised a fenestrated valve-clamp and forceps applicator, which render the operation extremely simple and devoid of danger. For the performance of his procedure the patient is placed in the knee-chest posture, and a proctoscope so adjusted that the border of the valve crosses the center of its aperture. The applicator carrying the open clamp having been introduced, the clamp is slipped well down over the valve and released, and the forceps and proctoscope are then withdrawn. The clamp should divide the valve in from four to six days (the time depending on the amount of fibrous tissue present), and when it is then discharged with the feces it carries the section of tissue within its grasp.

This clamp operation can be painlessly performed in the office in from one to five minutes. It is attended by no danger of hemorrhage, infection or complications; no dressings are required, and the patient, who is not detained from his usual vocations, suffers but little, if any, discomfort. Furthermore, it is more effective than the cutting operation, since it removes a section of tissue nearly half an inch wide and about an inch long, thus insuring wide separation of the remaining segments of the valve. Valvotomy, while unquestionably indicated in certain instances, is not called for in so

large a proportion as its most enthusiastic advocates would have us believe. In cases of long duration it is sometimes necessary, after the rectal valves have been divided, to properly educate the patient, and carry out the various other measures mentioned in order to overcome the habitual constipation. In conclusion Dr. Gaut stated that in his experience the results obtained from the non-medicinal method were far more satisfactory than those following the use of drugs.

DISCUSSION.

DR. ROBERT T. MORRIS said he at first felt suspicious as to the rectal valves constituting an obstruction to the passage of feces. He was skeptical because some of his friends failed to find these valves at all. Afterwards, however, he had himself seen them congested and thickened, and it seemed to him hardly possible that any one who had observed them in such a condition could deny their evident mechanical agency in promoting chronic constipation. The results were certainly very marked in a number of cases which he had seen operated upon. As to the proportion of instances in which valvotomy was of value, this could be determined only from statistics very carefully collected by experts. It was his own conviction that the percentage was fairly large. In his personal experience he had found that in a number of cases in which he had expected prompt relief from the procedure, the good results had not been so prompt as he could have desired. In other instances, however, immediate relief had resulted. There could be no question, he thought, that the condition of the valves spoken of in the paper constituted the chief factor in the distress from which a certain number of individuals suffered all their lives. He here referred to the case of a young lady of a wealthy family who had been a lifelong sufferer from obstinate constipation. She had had for many years the best medical advice both in this country and abroad, yet her condition remained unimproved. By valvotomy, however, she was instantly and permanently relieved. If, therefore, his procedure acted so favorably in only one case out of a hundred, he thought it was deserving of recognition as a valuable resource.

DR. EDWARD W. PETERSON said chronic constipation was both a symptom and a cause of a number of rectal as well as constitutional affections. In order to get a satisfactory result it is necessary to treat all the factors of the condition, whether local or general. It is well known that constipation frequently results from the passive congestion due to cardiac disease or cirrhosis of the liver, and also from the muscular relaxation which often follows acute diseases. Here it is of service to use mechanical means to give tone to the intestine, and the various measures referred to by Dr. Gaut are valuable adjuncts to the treatment. But these will prove inefficient in cases where the trouble is due to another class of cases, such as leadpoisoning, for instance, where antidotes to the poison must be resorted to. There are many cases where constipation results from reflex influence, and we should always endeavor to find out the real cause.

DR. C. F. WAINRIGHT said that while he could in general heartily endorse the views expressed in the

paper, there were manifold causes for constipation which could not be reached by the methods described. Especially is such treatment inadequate in those cases which have to do with the circulation, as where there is a vascular stasis on account of obstruction of the portal circulation. The same is true where constipation exists in connection with pulmonary conditions, and particularly tuberculosis. Again, it may be present in consequence of relaxation of the abdominal walls, and here the strapping of the abdomen, as advocated by Dr. A. Rose, is often followed by good results in patients who have been constipated for years. The function of the rectal valves is an important one, and it is the duty of physicians to see that the surgeons do no harm by cutting. It still remains to be seen whether valvotomy may not be followed by injurious results, in consequence of the lack of support thus withdrawn from the rectal walls.

DR. E. WALLACE LEE said he had been particularly interested in the rectal valves, which assumed prominence not only in constipation, but also in diseased conditions of the rectum and anus, such as hemorrhoids, fistula, etc. In such he had often looked for them, and in no single instance had he failed to find them. In fact, he had found congestion and hypertrophy of all the tissues composing the rectum. He was not enough of an anatomist to say whether the valves were a normal feature of the rectum or constituted a pathological condition. Whether they could strictly be called valves or not, he must say that he had never seen any reason to believe that they were anything more than simply folds of thickened mucous membrane.

DR. JOSEPH FRAENKEL spoke of the very great frequency of constipation in association with neurasthenia and hysteria, and said he had never seen a case of these in which it was not present. When patients suffering from disease of the heart, lungs or liver came for advice, they did not ask to be treated for their constipation, which was simply incidental. Neurasthenic and hysterical patients, however, applied to the physician expressly to obtain relief from constipation. In these cases he left the nerves to take care of themselves, and devoted his attention to the intestinal condition. He believed that chronic constipation was a disease *per se*, and that the great cause of it was rachitis. Most rachitical persons, he said, were born constipated, and he believed that over 90% of those who suffered from habitual constipation were the subjects of rickets. Concerning the mentioned hypertrophied valves, he was convinced that these were merely a result of constipation.

DR. L. F. BRIDGEMAN spoke on the medicinal treatment of habitual constipation. He said he always told his patients, if they did take a laxative, to take it regularly every day, and not simply at times when they were particularly constipated. Personally, he relied chiefly upon cascara, and his favorite preparation was an aromatic fluid extract. The patient was instructed to take every night a dose sufficient to produce a movement the next morning. This daily quantity was continued for a considerable time, and then gradually reduced. In this way a good many cases were permanently cured, and a good many not. He thought we must depend pretty largely on moral influence in the treat-

ment (the patient must be trained), and all physicians recognized the importance of measures other than drugs.

After several others had taken part in the discussion, it was closed by Dr. Gaut, who said that his paper had been by no means intended as a surgical one. In the great majority of cases he depended entirely on the various measures of hygiene to which he had alluded, and resort was had to surgery in exceptional instances only. He had made no attempt to deal with the etiology. He had treated of habitual constipation from carelessness on the part of the patient. Reference had been made in the discussion to toning up the intestinal muscular fibers by means of medicines, but he believed that this could be accomplished better by massage and systematic indoor and outdoor exercise. Valvotomy was sometimes justifiable, but, as he had stated, was not called for as frequently as some enthusiasts would claim. As a matter of fact, he himself performed it oftener in cases of colitis than of constipation. In colitis, by the obstruction of the bowel which they presented, the valves not infrequently caused detrimental accumulations of mucus. The rectal valves, he wished to say, were found to be normally present in the fetus, in the infant and at every age throughout life. He felt confident that he could demonstrate them in any individual to the entire satisfaction of the most skeptical. He had never examined the rectum of a patient without finding them. There were usually three valves, but sometimes four, and they passed most of the way around the walls of the bowel. In order to observe them, it was necessary that the rectum should be distended, and they could be readily seen in any individual in the knee-chest position when a proctoscope four inches long was employed for the examination. With a small speculum they might easily escape notice. These valves were not simply folds of mucous membrane, but were constructed of three coats, — mucous, fibrous and muscular, the latter consisting of both longitudinal and circular fibers. As regards the use of medicines, it was very difficult to effect a cure by them, and, in most instances, they had to be continued indefinitely. In the case of cascara he had sometimes found the drug to set up a catarrhal condition of the intestinal mucous membrane. Personally, he had not given a drop of medicine in this class of cases for over ten years. A permanent cure could usually be brought about by the non-medicinal method, but for this it was absolutely essential that it should be carried out systematically for a considerable length of time. He therefore made it a point never to undertake a case in which the patient would not pledge himself to take the treatment for a definite period.

Recent Literature.

The Medical Epitome Series. Obstetrics. A manual for students and practitioners. By W. P. MAXTON, M.D., Adjunct-Professor of Obstetrics and Professor of Clinical Gynecology, Detroit College of Medicine, etc. Series edited by V. C.

PEDERSEN, A.M., M.D., Clinical Assistant in Surgery at the New York Polyclinic Medical School, etc. Illustrated with 82 engravings. Pages 265. Philadelphia and New York: Lea Brothers & Co.

The author says in the preface that in a work of this scope only the essentials of obstetrics can be presented. The reviewer would qualify the author's statement by saying that only the barest outlines of the essentials of obstetrics can be presented.

The book is undoubtedly intended and arranged for a quiz, and as such and as a short cut to the examination should not be encouraged. It has been decreed that there are no short cuts to knowledge, and why, therefore, should there be to the examination paper, supposedly a test of knowledge?

The book as it appears, however, is one of the best of its class, and the author has written a text that, as far as it goes, very little exception can be taken to.

The Mycology of the Mouth. By KENNETH WELDON GOADBY, D.P.H., L.R.C.P., M.R.C.S., L.D.S., Bacteriologist and Lecturer on Bacteriology, National Dental Hospital, etc. London, New York and Bombay: Published by Longmans Green & Co. 1903.

The student of mouth bacteria will find more interesting and useful information compressed into the 220 odd pages of this work than in any work of a similar nature that has yet appeared.

The first five chapters are given up to the classification of the micro-organisms usually grouped under the general heading of bacteria. Attention is called to the methods of growth, and the influences which encourage development and those which retard it. Three chapters describe the usual laboratory methods, and call attention to the utensils needed for laboratory work. This part of the book is much the same as that which one usually meets with in most of the textbooks on the subject.

The chapter on immunity and susceptibility is inadequate, as might be expected in so brief a work.

The value of the work lies largely in its accurate descriptions of a number of mouth forms which have not been adequately described in other books, and we regret that the list is not a longer one and the identification carried out even more fully. It is a step in the right direction, and the book marks an advance in the study of the subject.

The author quotes liberally from other writers, giving full credit and in many instances giving the name and page of the volume referred to. This brings a great amount of valuable information to the reader's notice, and enables him to refer to the original volume for more detailed knowledge.

The book does not throw much new light on the influence of specific forms in the various diseases of the mouth and teeth, and in this is disappointing. It is only by the expenditure of an enormous amount of time that such problems can be worked out, and this book will serve as a useful guide to the student in doing such work.

It is also of interest to the general practitioner, and the intelligent dentist will find between the covers, in a simple form, that which he wishes to know and that which he ought to know concerning the mycology of the mouth.

The Elements of Bacteriological Technique. A Laboratory Guide for the Medical, Dental and Technical Student. By J. W. H. EYRE, M.D., M.S., F.R.S. (Edin.); Bacteriologist to Guy's Hospital, London. With 170 illustrations. Philadelphia and London: W. B. Saunders & Co. 1902.

This is an admirable book. It is sure to find favor with all workers in bacteriology. The various procedures are clearly yet concisely described. The numerous illustrations are instructive, and are nearly all original. As the author says, a picture, if good, possesses a higher educational value and conveys a more accurate impression than a page of print. Among the chapters of special merit are those on staining methods and methods of identifications. A portion of the book is arranged to furnish the outlines of a course for laboratory classes. Under each exercise a detailed list of the apparatus required is given.

The advances in technique made by American bacteriologists are recognized and incorporated. The use of phenolphthalein, instead of litmus, as the indicator for the reaction of media, is advocated. A standard reaction $+1.0$ is recommended; although this is lower than that of the American Committee of Bacteriologists, it is too highly acid or the optimum growth of most pathogenic bacteria. The descriptive terms for cultural appearances introduced by Chester have been adopted.

The preparation of blood serum as described in this and most other laboratory guides is a difficult and time-consuming task. The simple and satisfactory method devised by Councilman and Mallory is not mentioned. Blood serum prepared by their method is not only easy to make, but is probably the best for the routine examinations of pathological material. It can be sterilized in the autoclave.

Physical Chemistry for Physicians and Biologists. By DR. ERNST COHEN, Professor of General and Inorganic Chemistry in the University of Utrecht; authorized translation from the German by MARTIN I. FISCHER, M.D., Instructor in Physiology in the University of California. New York: Henry Holt and Company. 1903.

This book is a good introduction to the science of physical chemistry as applied to physiological chemistry. It is clear and comprehensible, and especially well adapted for the use of physiological experimenters and of physicians who wish to make themselves acquainted with the facts and theories on which are based new methods of diagnosis dependent on physical chemistry such as cryoscopy.

M. V. T.

An Introduction to Dermatology. By NORMAN WALKER, M.D. Second edition. Revised and enlarged. New York: William Wood & Company. 1902.

In the second edition of Dr. Norman Walker's work we find a considerable number of new cuts and illustrations of varying degrees of excellence. As was emphasized in the preface to the first edition, the book embodies the substance of the writer's lectures to elementary students, and as such serves its purpose very well.

THE ETIOLOGY OF SMALLPOX.

At a meeting of the Boston Society of Medical Sciences, held April 28, at the Harvard Medical School, Dr. W. T. Councilman announced the discovery of the probable etiology of smallpox. The work which has led to this announcement, the importance of which can hardly be overestimated, has been carried on for the past two years by Drs. W. T. Councilman, G. B. Magrath and W. R. Brinkerhoff, with the assistance of Dr. E. E. Tyzzer and others, at the smallpox hospitals of Boston and at the pathological laboratory of the Harvard Medical School. The material for the investigation was provided through the co-operation of the Board of Health, from the epidemic of smallpox which visited the city during the winter of 1901-02.

Bodies of uncertain origin and significance, for upward of ten years, have been observed in the epithelial cells of the skin in cases of smallpox. Inasmuch as no life history of these bodies could be made out, opinion varied as to whether they were actually organisms or merely indicative of cellular degenerations. In general the latter opinion prevailed. Dr. Councilman and his co-workers, going over this work and carrying the research much further, have been able to demonstrate the fact that these bodies are certainly organisms, belonging to the group of the protozoa, and further, that they have a definite life cycle, both without and within the nuclei of the deeper layer of epithelial cells of the skin.

The following points were clearly brought out in Dr. Councilman's admirable exposition of the results of the investigation:

That smallpox passes through certain perfectly definite stages in its development on the clinical side, to which correspond equally definite changes in the form of the causative organism; that these

changes in form consist first in the appearance in the cell protoplasm of small, homogeneously staining, structureless bodies, about one micron in diameter, not staining so deeply as nuclei, which gradually increase in size, coincidently with the degeneration of the cells in which they lie; that with this increase in size the character of these bodies changes, small granules surrounded by circles appear in them, the general outline becomes irregular, with increasing resemblance to an ameba; that a process resembling sporulation takes place with the breaking up of the ameboid forms into smaller, sporelike bodies; and that this constitutes the first cycle in the life of the organism. Up to this period the nuclei of the epithelial cells show no changes whatever, but the following alterations in these structures now appear: penetration of nuclei by the small sporelike bodies before spoken of, with the disappearance of such bodies from the cell protoplasm; small ring-shaped bodies become apparent in the nuclei; they also increase in size; the ring shape is at first preserved, which is soon surrounded by a spongelike body. This whole structure grows, fills and finally destroys the nuclei, and the bodies become free; the bodies again become more homogeneous; ring-shaped bodies again become evident; finally each ring appears to have a central dot. These final bodies are regarded as the infecting agent of the disease. Two cycles of the organism, corresponding in general to what we know of the protozoa, have therefore been demonstrated: the first — extranuclear — simple, and the second — intranuclear — very probably sexual.

It also appears to be demonstrated by this work that vaccinia represents the extranuclear phase of the organism, but that the production of true smallpox is dependent upon the invasion of the nuclei — the intranuclear cycle. Vaccinia may be produced by inoculation, for example, in the calf or the rabbit; variola under similar conditions is produced in the monkey. This, also, Dr. Councilman and his colleagues have shown. The organism was found in the blood in one case. The difficulties of study are very greatly increased by the extreme rapidity with which the entire process takes place and by the ease with which the organisms are destroyed; the life history is completed with the formation of the vesicle, hence the absolute necessity of securing early and perfectly fresh material. The rôle of bacteria is regarded as entirely subordinate to the organism described, though the influence, particularly of streptococci, must be taken into consideration in the development of the disease.

Dr. Councilman expressed the opinion with confidence, that the organism which he described belonging to the protozoa was the essential etiological

factor in the production of smallpox. This opinion received confirmation from the apparently conclusive lantern-slide demonstration, illustrating phases in the life history of the organism, and also from the testimony of Prof. G. N. Calkins of Columbia University, who was present, and who had previously identified certain of the ameboid forms as unquestionably protozoa. Professor Calkins' recognized knowledge of the protozoa adds weight to the statement he made at the meeting, that "there is absolutely no doubt that we have to do in the process with an organism which belongs to the protozoa."

It requires no stretch of the imagination to see in this work of Dr. Councilman and his assistants a discovery of the most far-reaching significance. If it stand the test of criticism, which will forthwith be turned upon it from all parts of the world, it must unquestionably be regarded as one of the great medical discoveries. If, in the future, it requires modification, it will still stand as an investigation of vital importance for having directed attention to the probable great significance of the protozoa in the production of diseases, for example, the exanthemata, which have hitherto wholly eluded the most painstaking research. The enthusiastic reception which the preliminary announcement received at the hands of the representative audience to whom it was addressed, will no doubt forthwith find an echo wherever scientific work is appreciated.

ARSENIC IN LIVING ORGANISMS.

IN the pursuit of medico-legal examinations of bodies for the detection of poisons, as well as in the examination of food preparations and drugs for arsenic, which is sometimes present as an accidental impurity, the chemist is often confronted with the argument that this poison exists as a normal constituent of many living organisms.

If this is the fact, it is desirable to know to what extent arsenic enters into their composition, in order that comparison may properly be made between quantities which are possibly normally present and those which are introduced either accidentally or intentionally.

In a recent paper Dr. Bertrand¹ considers this question, his object being to determine the amount of arsenic present in living organisms, existing under perfectly normal conditions, and to find out whether arsenic is a primordial element of the living cell, as much so as carbon, nitrogen and other elements.

It was necessary to make observations under the

¹Nouvelles recherches sur l'arsenic de l'organisme. Par M. Gabriel Bertrand. *Annales de l'Institut Pasteur*, January, 1903.

most severe conditions, upon animals living in a normal medium, and entirely free from the conditions which exist upon land where arsenic enters into the operations of agriculture and other industries to a large extent. For this purpose the cetaceans, sea-birds, fishes and animals which inhabit the depths of the sea presented favorable opportunities for such examination.

All of the specimens were taken, and much of the chemical work was performed in the course of a cruise undertaken for scientific purposes, in the summer of 1902, on board the yacht "*Princess Alice*," with the exception of the sheep, which came from the pastures of Mt. Pico, and the grampus, which was harpooned by the Prince of Monaco in the Mediterranean Sea. All the other specimens were collected from the sea, mostly by dredging, in an area bounded by Gibraltar, the Azores and the British Channel. Precautions were taken not to soil the specimens. The dissections were made upon a wooden table. The birds were shot and the feathers only were examined, since leaden shot usually contain arsenic. Some of the specimens were collected from the bottom, at a depth of one mile or more.

The reagents were carefully examined to ensure the absence of arsenic. Many of the analyses were made at sea during the cruise, and some of them were repeated at the Pasteur Institute after returning; in all instances the results of the latter confirmed the former.

The following table presents the results of the examinations, including the following points: (1) the name of the animals examined; (2) the organs or parts examined; (3) weight of the material submitted to analysis; (4) weight of reagents employed; (5) amount of arsenic found:

| Name of species examined. | Organs or parts examined. | Weight of dry matter exam'd in gms. | Weight of reagents empl'd. | | Arsenic found in mgm. |
|---------------------------|---------------------------|-------------------------------------|----------------------------|--------------|-----------------------|
| | | | Nitric Acid. | Sulp'c Acid. | |
| Sponge . . | Entire. | 36.7 | 67.5 | 17.5 | .005 |
| Actinia . . | Entire. | 13.1 | 18 | 7 | .002 |
| Starfish . . | Entire. | 29.0 | 40.5 | 19.5 | .002 |
| Sea-urchin . | Entire. | 30.4 | 32.5 | 33.5 | .0045 |
| Poliothuria. | Entire. | 81.8 | 72 | 15 | .003 |
| Crustaceans . | All except the shells. | 31.5 | 147 | 26 | .002 |
| Small fish . | All except the bones. | 40.8 | 81 | 14 | .002 |
| " | Testicles. | 12.5 | 16 | 7 | .0015 |
| Tunny . . | Skin. | 26 | 180 | 40 | .0035 to .004 |
| " | Skin. | 24.7 | 45 | 15 | .0025 to .003 |

| Name of species examined. | Organs or parts examined. | Weight of dry matter exam'd in gms. | Weight of reagents empl'd. | | Arsenic found in mgm. |
|---------------------------|---------------------------|-------------------------------------|----------------------------|--------------|-----------------------|
| | | | Nitric Acid. | Sulp'c Acid. | |
| Tunny . . | Skin. | 32.7 | 36 | 14 | .005 |
| " | Muscle. | 30.1 | 71 | 14 | .0015 |
| Sea-bass . . | Skin. | 22.2 | 45 | 12 | .001 |
| " | Muscle. | 17.1 | 33 | 8 | .001 |
| " | Scales. | Ab't 20 | 33 | 8 | .001 |
| Sea tortoise, | Scales. | 20 | 40.5 | 9.5 | .0035 |
| Petrel . . | Feathers. | 34 | 43 | 15 | .0025 |
| Grampus . | Horn. | 50 | 45 | 10 | .0025 |
| " | Epidermis. | 40 | 86.5 | 19.5 | .0035 |
| " | Skin. | 11.4 | 36 | 9 | .002 |
| Sheep . . | Thyroid gland. | 20 | 50.5 | 10.5 | .001 |

Bertrand adds that specimens of sand dredged from the bottom at different depths, and dried, gave variable results, in one instance a scarcely perceptible trace, and in another, collected from a depth of 1,187 meters (two thirds of a mile), furnished an arsenical ring of about four to five thousandths of a milligramme, the specimen weighing 38 gm. He concludes from this and other similar researches that arsenic exists as a fundamental element of living organisms, and believes it necessary, in all medico-legal investigations, to make careful quantitative analyses, and not to be content with merely determining the presence of arsenic.

THE ANNUAL REPORT OF THE MASSACHUSETTS GENERAL HOSPITAL.

THE eighty-ninth annual report of the Massachusetts General Hospital for the year 1902 has recently appeared. The total number of patients treated at the institution, exclusive of the Out-Patient Department, was 5,199 as against 5,353 in 1901, giving a daily average of one less than in the previous year. A somewhat smaller number of free patients were treated than in 1901, and about 1,800 patients paid in part or in full for their treatment. There was a certain increase, however, in the cost per patient, due to the increased price of various necessary supplies. In the Out-Patient Department 27,662 new patients were treated, five less than in 1901. The number treated in the accident room was about 1,000 less than in the previous year, due, no doubt, in a measure to the establishment of the Relief Station of the City Hospital in Haymarket Square. It was expected that the falling off in this department of the hospital's work would be much greater.

Several buildings, which have been in process of

construction for the past few years, are now fully equipped and in use. It is worthy of note that a ward, to be known as the Weld Ward, for the treatment of diseases of the skin and certain other diseases, has been completed, though it has not yet been put into active service. A children's ward has also been added to the hospital, so that a further classification of the patients than has hitherto been possible may now be made. It is expected that the new out-patient building will be ready for occupancy sometime during the summer. When this is accomplished, the facilities, both for the adequate treatment and study of patients and for teaching, will be very greatly increased. Work for several years past in the present quarters of the Out-Patient Department has been done under great and increasing difficulties. The establishment of so complete and commodious an out-patient department as this promises to be is a further indication of the significance to the hospital at large which the treatment of ambulant patients is coming to have. The mere dispensary is by degrees giving place to adequately equipped departments for the proper study of so-called dispensary patients.

A number of pages of the report are taken up with the consideration of the instruction in the training school for nurses. The system which is now in vogue went into effect Feb. 1, 1902. The general medical and surgical instruction in nursing is under the charge of two physicians, who devote a very considerable amount of time to the work. The course is intended to be more systematic than hitherto and to go somewhat further into the clinical manifestations of disease than perhaps has ordinarily been taught in training schools. Section work for the nurses is adopted, and the clinical material in the wards has been used to illustrate important practical points. We have no doubt that this method is correct in principle and feasible in practice. It is simply a further recognition of the fact of the necessity of first-hand knowledge in the practical medical work of nursing.

The report of the McLean Hospital is as usual full of suggestions for the further development of psychiatry. The public is coming to look to this report for a general expression of progressive views, both in the treatment and in the study of the insane. The present report is no exception to the standard which has hitherto been set. The important needs of this branch of the hospital are a house for women patients and a special fund for permitting the scientific study of the causes, treatment and prevention of insanity.

A large section of the report is taken up with medical and surgical statistics elaborately classified. The Out-Patient Department is not entirely neg-

lected, although two departments give merely the number of patients treated without details as to the character of their diseases. In the classification of the occupations of patients admitted to the hospital exception may with justice be taken to the use of the word "salesladies." As an occupation, also, 57 are put down as "spinsters," and 115 as "widows." This is possibly a questionable use of language.

GOVERNMENT LABORATORIES IN MANILA.

We have from time to time commented on the needs of medicine and on the opportunity offered for investigation in the Philippines. The recent report of the superintendent of government laboratories for the year ending Aug. 31, 1902, gives many suggestions which are of practical interest to the development of medicine in general. It appears that only a few years ago such government laboratories as existed in the Philippine Islands had but a small stock of apparatus, a meager library, and were housed on the ground floor of a building which had been rented for the use of the civic hospital. Less than two years ago the necessity was felt of providing a better building for laboratory purposes. This was provided, and necessary journals and apparatus were introduced from America and Germany. It is now felt that the present quarters, although an improvement over the preceding, are altogether inadequate for the extended work which the medical department is called upon to do. A new plan has, therefore, been drawn up which will provide laboratory space for chemical and biological laboratories and for a serum institute. This will consist of sixty rooms. So far as one can see, from looking over a description of this building, it should fully meet the present demands and any future demands that may be made upon it, at least for many years. In planning the laboratory building and its equipment it has been kept in mind that the opportunities for investigation of tropical disease, and of related problems, will induce scientific men of high attainments to resort to Manila for the prosecution of their researches. It is pointed out that hitherto various expeditions have been fitted out at very considerable expense to investigate the diseases of the tropics. Hereafter by the establishment of adequate laboratory facilities it is hoped and expected that such investigations can be carried out less expensively and more effectually. It is unquestioned that the active work being done by men prominent in the medical profession in the Philippines has been not only a stimulus to professional men already in the islands, but also to men of ambition in various parts of the world. Particularly

is there an opportunity for young men of good training and promise of scientific attainment, who find small opportunity for work in the crowded medical centers of their own country. We have no doubt that the establishment of a laboratory as proposed will go far toward attracting men of ability to what must certainly prove to be a rich field of investigation.

MEDICAL NOTES.

JAPANESE ANTHROPOMETRY.—In 1878 the government of Japan requested President Seelye of Amherst College to detail a competent person to go to Japan and spend at least three years for the purpose of instituting the Amherst system of physical culture in the schools of Tokio. Dr. George A. Leland was selected for this work, and some of the results, which will be of interest to students of anthropometry, have been embodied in a table which has been published.

THE INDEX MEDICUS.—We have several times called attention to the importance of financial support for the *Index Medicus* from the profession and from medical libraries. A medical subscription of \$1,255 goes but a little way towards the annual sum required—about \$12,000. Let us show an appreciation of our blessings ere they again take their flight.

FOURTH PAN-AMERICAN MEDICAL CONGRESS.—At a meeting of the International Executive Committee of the Pan-American Medical Congress, held April 1, 1903, it was decided to accept the proposal of the Argentine Republic to hold the Fourth Pan-American Medical Congress in Buenos Ayres, in 1905, instead of 1903, as had been announced in their invitation of February, 1901. This was considered by the committee much more advantageous for the meeting, as it has long since been realized that it would have been impossible to have had a good representation of the delegates from this and other countries had the convention been held there in June of this year.

The meeting of the American Medical Association in New Orleans and of the Congress of Physicians and Surgeons in Washington would have prevented a number of physicians of this country from attending; while the meeting of the International Medical Congress in Madrid would have probably attracted many from the Spanish-American countries who would otherwise have been disposed to have taken an active interest in it.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, April 29, 1903, there

were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 18, scarlatina 36, typhoid fever 14, measles 27, smallpox 0.

BOSTON MORTALITY STATISTICS.—The number of deaths reported to the Board of Health for the week ending April 18 was 220 as against 243 the corresponding week last year, showing a decrease of twenty-three deaths, and making the death-rate for the week 19.57. The number of cases and deaths from infectious diseases was as follows: Diphtheria, 26 cases, 6 deaths; scarlatina, 25 cases, 1 death; typhoid fever, 9 cases, 1 death; measles, 3 deaths; tuberculosis, 25 cases, 22 deaths; smallpox, no cases. The deaths from pneumonia were 36; whooping cough 4; heart disease 16; bronchitis 5, and marasmus 2. There were 12 deaths from violent causes. The number of children who died under one year was 33; under five years 61; persons over sixty years 45; deaths in public institutions 76.

VERDICT FOR DEFENDANTS IN A SUPPOSED UNAUTHORIZED AUTOPSY.—In a suit recently brought against the Massachusetts General Hospital, to recover damages for an autopsy upon a Hebrew, a verdict has been returned for the defendants. It was claimed by the family of the patient that the autopsy had been performed without permission. The evidence, however, showed that through a misunderstanding it was believed that permission had been granted.

NOMINATION FOR BOSTON BOARD OF HEALTH.—Among a number of appointments about to be made, the mayor of Boston has sent the name of Dennis J. Hern to be a member of the Board of Health, in place of Robert Cox, whose term expires April 30. Mr. Hern is reported to have accepted the nomination.

BEQUEST TO THE SHARON SANITARIUM.—The Sharon Sanitarium has recently received \$10,000 from the Billings Fund.

BEQUEST TO THE NEW ENGLAND BAPTIST HOSPITAL.—By the will of Phebe R. Sturtevant the New England Baptist Hospital receives \$10,000.

AMERICAN SOCIAL SCIENCE ASSOCIATION.—The meeting of the American Social Science Association will be held in Boston, May 14, 15 and 16. One section of the Association will devote itself to the discussion of questions relating to preventive medicine and matters of general medical interest. This section is under the chairmanship of Dr. S. H. Durgin. Dr. E. M. Hartwell, Prof. W. T. Sedgwick, Prof. Theodore Hough and Dr. W. T. Councilman are expected to take part in this meeting.

DR. SAMUEL FULLER OF THE "MAYFLOWER," 1620. — Dr. Thomas F. Harrington of Lowell Mass., read a paper before the Johns Hopkins Historical Society at Baltimore, Monday evening, April 20, entitled "Dr. Samuel Fuller of the 'Mayflower,' 1620. The Pioneer Physician of America."

NEW YORK.

RESIGNATION OF DR. DOREMUS. — At a meeting of the Board of Trustees of the College of the City of New York, held April 11, the resignation was accepted of Dr. R. Ogden Doremus, for many years professor of chemistry in that institution, and also for many years in Bellevue Hospital Medical College.

FACSIMILE OF EARLY MEDICAL PAMPHLETS. — A series of reproductions in facsimile of early medical pamphlets is announced, to be issued under the editorial supervision of Dr. Albert T. Huntington, librarian of the King's County Medical Society, Brooklyn. The first of these will be a monograph by William Douglas, printed by Franklin at Boston, in 1722, entitled "The Abuses and Scandals of Some Late Pamphlets in Favour of Inoculation of the Small Pox, Modestly Obviated, and Inoculation Further Consider'd in a Letter to A— S—, M.D., & F.R.S., in London." There is to be an illustrated prefatory sketch (historical, biographical and bibliographical), written by Dr. Lewis S. Pileher. According to Dr. John S. Billings, we had at the commencement of the Revolutionary War but one medical book by an American author ("Plain, Precise, Practical Remarks on the Treatment of Wounds and Fractures," by Dr. John Jones, New York, 1775), three reprints and about twenty pamphlets. This monograph is one of the latter, and the earliest of the pamphlets is a broadside written by the Rev. Thomas Thatcher, the first minister of the "Old South" in Boston, dated January 21, 1677-8. The title is "A Brief Rule to Guide the Common People of New England How to Order Themselves and Theirs in the Small Pox, or Measels."

TENEMENT-HOUSE BILL. — The governor has signed the new tenement-house bill. This measure is the result of a compromise between those who sought a modification of the existing law and Mr. De Forest, the tenement-house commissioner. While the latter was willing to grant some concessions, he took a firm stand as to yielding any essential points in the improved construction of tenements. In this position he was backed up by the sentiment of the community, and the result is to be regarded as a victory for the health and welfare of the poor over greed. The amendments will permit a semi-fire-proof construction in four-story tenements having

not more than two families to a floor, with apartments running through from front to rear, and with courts of such a size that the buildings may be erected on lots twenty-five feet in width. This, it is believed, will reduce the cost of such a building by about \$1,000, thus lowering the rentals. In buildings of three stories, covering not more than 65% of the lot area, a slightly smaller interior court is allowed. Outside the fire limits the law will permit the erection of wooden tenements of three stories, to contain not more than one family to a floor.

CHILD LABOR BILL. — The governor has also signed a child labor bill which forbids the employment in or in connection with any factory in the State of any child under sixteen years of age without a certificate issued by the local health authorities, showing its age and that up to the age of fourteen it has attended school for the equivalent of 130 days in the school year. It limits the employment of children to fifty-four hours in any one week and nine hours in any day. It also limits the work of women to sixty hours in a week or ten hours in a day.

Correspondence.

LETTER FROM THE PHILIPPINES.

SPECIAL CORRESPONDENCE.

RAIDS ON UNSANITARY BARBER SHOPS, SQUATTERS AND OPIUM "JOINTS." — THE HABIT OF OFFICIAL CORRUPTION. — THE PHILIPPINE CENSUS. — PLAGUE AND THE HAFKINSE SERUM. — DR. HAN KEE, AN ENGLISH-SPEAKING CHINESE DOCTOR. — THE CARE OF THE PERSON IN THE TROPICS. — BENZOZONE AS A STERILIZER. — LOW STANDARD OF SURGICAL PRACTICE IN PHILIPPINES.

MANILA, March, 1903.

MR. EDITOR: There has lately been some wholesale raiding by the police, acting under instructions of the Board of Health, of unsanitary barber shops in Manila. In one district, more than forty Chinese and Filipino barbers were arrested in a single day for violation of a sanitary regulation requiring the sterilization of all instruments and brushes, the use of good soap, and cleanliness of the hands and the wearing of white coats by the barbers. This regulation, passed some time ago, has been completely ignored by the Chinese and Filipino "tonorial artists," and hence the recent arrests. There is much skin disease in Manila, and the unsanitary barber shops have been rightly regarded as one of the chief factors in its transmission.

A number of native families now squatting on unoccupied government land on Calle San Marcelino are to be shortly removed by the authorities because of the unsanitary condition of their houses and surroundings. This action was taken at the instance of the Manila Board of Health. In order not to work too great hardship on the natives to be removed, a tract of government land in the Paco district is to be divided into small plots, and such of the evicted families as desire to take advantage of the privilege can rent one of these new building sites at a small cost. The proposed action is in line with the constant effort of the health authorities to do away as rapidly as possible with the congestion and highly unsanitary conditions existing in certain of the native districts of the city.

A sanitary crusade has also been started by the health officials against the many filthy opium dens in the Chinese districts of the city. These "joints" are all in a

highly unsanitary condition, and the police and health department are co-operating in the effort to break them up or at least place them in a more cleanly condition. Of course the effort is not regarded with favor by the Chinese proprietors.

Like the other departments of the government over here, the sanitary service still feels the influence of the official corruption so rife under the Spanish administration, when the enforcement of laws was not carried out so long as some official could have his pockets lined as a result of his leniency. The Malay expects all officials to be open to bribery, and the Chinese can understand no system based on simple right and justice. Efforts to bribe the sanitary inspectors, by both Filipinos and Chinamen, are still not rare, and when the sanitary service was first organized the handing over of a few Mexican dollars to the inspector was rather the rule than the exception. The Filipino inspectors did not hesitate at first to take advantage of their opportunities, and the system of corruption was finally broken up only by summary discharge and careful supervision of the manner in which the inspection duties were performed. At present, subordinate sanitary inspectors are assigned to districts and held responsible for sanitary conditions within those limits. Their work is verified by medical inspectors, who are Americans. Should the latter find a house presenting an unsanitary condition, the report of the native sanitary inspector is looked up. Should this be favorable, the native inspector receives an official warning for what is either carelessness or an attempt at fraud, and should complaint be made against him a second time for similar cause, he is summarily discharged. With such a careful system of supervision, a subordinate sanitary inspector cannot receive bribes for failing to perform his duty without his dishonesty being soon detected and promptly punished. It is by measures like this that the old Spanish system of bribe-taking and bribe-giving is being broken up, and the native, in spite of himself, is being brought to occupy a position of inflexible official honesty. One obstacle to the improvement of the natives in respect to honesty in the Board of Health as well as other departments was found in the character of many of the Americans first appointed to positions under the civil government. Some of these were political adventurers, of no standing at home, and desirous of filling their pockets by hook or crook — usually by both. These men, at the onset of affairs, exerted a bad influence on the natives, but as fast as their undesirable character was determined, the civil government has put better men in their places.

The enumeration for the Philippine census began on March 2, and is being pushed as rapidly as possible. This census will have results especially valuable to the sanitary work in forming a reliable basis for sanitary statistics, and in the creation of a more satisfactory sanitary organization throughout the islands. At present the statistics for sickness and death have been based on estimates of population and thus could not be regarded as accurate.

Many cases of plague are continually cropping up in Manila in spite of the efforts of the health authorities. In nearly every case that occurs the infection appears to have taken place through some lesion of the foot or lower extremity in the barefooted Filipino or Chinaman. So many Chinese have been attacked that the Board of Health has been obliged to give up the practice of cremating Chinese plague corpses, and these are now covered with quicklime and enclosed in hermetically sealed metallic coffins for burial. The Chinese are thoroughly opposed to cremation as a method of disposal of the dead, as all desire to have their bones interred in China. The Board of Health is anxious to secure the good will of the Chinese as far as possible, and for this reason cremation has been abandoned and metal coffins supplied at the expense of the municipality.

Word comes from India that bubonic plague is very severe in certain districts there. The Haffkine preventive inoculation has been largely employed under government auspices and seems to have much effect in preventing the development of the disease. Unfortunately, Haffkine himself is said to have lately been guilty of gross carelessness in the preparation of his anti-plague serum, both as to the purity of the plague

cultures employed and as regards their subsequent sterilization. As a result, nineteen deaths from tetanus have been directly attributed to the use of contaminated and improperly sterilized serum, and the matter is now being made the subject of official investigation, with the probability that Haffkine will be proceeded against in the courts, or that the government will at least refuse to permit him to continue his work in India.

The services of Dr. Han Kee, an English-speaking Chinaman, educated at the English Medical-School at HongKong, have been secured by the Manila Board of Health as a medical inspector. He will pay special attention to plague among the Chinese, which disease is now on the increase, and will also be the medical superintendent of the Chinese hospital. The services of a properly qualified Chinese physician have been much needed in Manila, as the sixty thousand Chinese in the city have practically no good medical men of their own, and many of them speak neither English nor Spanish. They also regard with distrust any one not of their own race, and for this reason the Board of Health has been handicapped in its sanitary work among them. It is believed that the appointment of Dr. Han Kee will largely remove these obstacles.

As an aftermath of the cholera epidemic, a large number of claims have been presented to the government authorities of the islands for settlement. During the epidemic the sanitary officers, sent out by the general government in Manila to fight cholera in the provinces, hired natives as inspectors and nurses, seized buildings for use as cholera hospitals, and in many cases burned infected native houses as a means of staying the progress of the disease.

At the regular March meeting of the Manila Medical Society a paper was read by Dr. H. W. Yemans on the care of the person in the tropics. He believes that foreigners should dress more lightly during the hot days and more warmly during the cool nights. At present they are not as rational in their clothing as the Filipinos or Chinese, this particularly applying to the American women, who still retain the use of corsets and tight clothing. Chilling at night as a result of insufficient clothing is a great cause of diarrhea and menstrual disorders. While frequent bathing is to be commended, the use of much soap and friction with coarse towels is to be deprecated, as impairing the integrity of the outer protective epithelium and creating minute skin lesions, upon which the germs of parasitic skin diseases attach themselves and multiply rapidly. He believes that much skin disease results from this cause.

Dr. W. B. Wherry read a paper based upon work at the Government Pathological Laboratory relative to the sterilization of drinking water by the use of the new germicide, benzozone. He stated that when benzozone was present in the proportion of 1-60,000 and acted over a period of five minutes, all the micro-organisms found in the Manila water supply, with the exception of a few moulds and a few spores of the hay bacillus, were destroyed. On experimenting with the typhoid bacillus, as representing a class of non-sporulating micro-organisms to which the cholera and Shiga's dysentery bacillus also belonged, it was found that benzozone, in a solution having a strength of 1-60,000, absolutely destroyed the typhoid bacillus in water at the end of five minutes. As benzozone is completely harmless when taken internally, many persons in Manila having habitually used it in solutions of 1-2,000 strength for all drinking purposes during the cholera epidemic, the possibility of sterilizing drinking water by its use, as far as the pathogenic bacteria are concerned, is both interesting and important. It was found by Dr. Wherry that by substituting a 1-60,000 solution of benzozone for the distilled water now purchased for the San Lazaro Hospital, more than two hundred dollars per month could be saved to the government at this institution alone. Unfortunately, the action of dilute solutions of benzozone upon the ameba found in water is not yet understood, and amebic dysentery, which is always with us, is far more to be feared in the long run than cholera, which scourges the islands only about once in a generation.

An interesting statement, illustrating the low standard of surgical practice in the Philippines prior to the arrival of the surgeons with the American army, was

made to the society by Dr. Donelan, an English physician who had been in Manila for many years, on the exhibition by Dr. Banister of a case of gunshot wound of the intestine with recovery after operation, and the exhibition by Dr. McDill of a large multilocular ovarian cyst and large dermoid cyst, both of which he had removed from the same patient, a young Filipino girl. In his remarks, Dr. Donelan stated that prior to the arrival of the Americans he had never heard of a laparotomy in the living body having been performed in the entire Philippine archipelago.

“THE PREPARATION AND DISTRIBUTION OF ANTITOXIN BY THE MASSACHUSETTS BOARD OF HEALTH.”¹

BOSTON, MASS., April 24, 1903.

MR. EDITOR: I notice on page 431 of the BOSTON MEDICAL AND SURGICAL JOURNAL of the issue of April 16, 1903, an article signed Theobald Smith, M.D., that so seriously reflects upon my veracity, I feel in justice to myself and the public that it is my duty to reply to the same.

Dr. Smith says: “If such men as Mr. Bartlet shall be allowed to play havoc in the public press . . . I doubt that any well-trained men would be found willing to direct the work under such conditions.” Again, Dr. F. L. Morse, who is claimed by the Boston *Advertiser* to be an officer of the Board of Health, and is alleged to have said in the issue of the *Advertiser* of April 21, 1903, “Mr. Bartlet does not know the first thing about the manufacture of antitoxin, in my opinion, and is not competent to give an opinion on the subject.” I would like to say for the information of these gentlemen that I am a graduate with honors from the Massachusetts College of Pharmacy, a regularly incorporated institution, whose standing cannot be questioned. That I served on the Board of Trustees of this college, and was for some years chairman of its Committee on Education, and at one time its first vice-president; that I have done much original research work, especially in connection with digestive ferments, and was actively engaged in business as a pharmacist for thirty years.

I have taken special pains to inform myself by actual inspection regarding the very best and most scientific methods for preparing both antitoxin and vaccine virus under the very best modern aseptic conditions in the laboratories of Messrs. Parke, Davis & Co., and the H. K. Mulford Company. These plants are under the personal supervision of trained biologists and bacteriologists of the highest standing, free from the slightest taint of “commercialism.” The commercial aspect never enters into consideration in the *manufacture* of these products, and is only present when the goods are ready for sale on the market.

When we compare the precautions and methods pursued in these establishments with those of the Bussey Institute plant, to say the least, the latter compares very unfavorably with the former. Take, for instance, one precaution that the manufacturers take, that of immunizing the horses from tetanus; this precaution is not taken, as I understand it, at the Bussey Institute plant. Is it not due rather to good fortune than to any other fact that an epidemic of lockjaw has not followed the use of the serum made at the Bussey Institute, as happened by the use of the product of the Board of Health of St. Louis? And yet the Board of Health of St. Louis was just as confident that their product was perfectly safe before the accident happened. It is not possible for this to happen from the use of the products of the leading reputable manufacturers of today.

It is simply idle to contend that there is no need of preparing antitoxin under sanitary and aseptic conditions and to intimate that these precautions are taken by the manufacturers for mere show. The boards of health have preached the germ theory too long and too well for that, as physicians and others know. Dr. Smith complains that Mr. Bartlet discussed this matter in the public press. In reply to this, I will simply say, when the petitioners felt that their cause before the leg-

islative committee was a lost one, they, in despair, as a last resort, rushed into the press and abused me for exposing their weak points. It was then, and only then, as now, that I felt bound to reply, in order that I might not be misrepresented. Dr. Smith says that my remarks about antitoxin standards and filters are full of misstatements. All I have to say about that is, that these remarks were his and not mine. I simply quoted what he said to me. In this matter I am simply endeavoring to get at the facts in the case, and believe that nothing is gained in the end by trying to advance theories by suppressing facts.

In order to show you how inconsistent the statements of the petitioners have been during this controversy I quote the following:

Question to Mr. Lawrence, counsel for the petitioners, by a member of the Committee of Public Health: “The State Board, I think, takes the position that they want them to have facilities, laboratories and stable in which to prepare antitoxin and vaccine, do they?”

Answer, by Mr. Lawrence: “Yes, as I understand from my talks with Dr. Walcott and Dr. Abbott; the State Board of Health is not satisfied with the present condition of affairs.” (Hearing of March 12, 1903.)

Member of the committee to Dr. Theobald Smith (same hearing): “Are you satisfied with these stables?”

Answer: “The stable, so far as our experience goes, it seems to me that this is quite good enough after an experience of nine years, everything has gone entirely satisfactory.”

Now let us look at Dr. Smith's statement in the article of the BOSTON MEDICAL AND SURGICAL JOURNAL for April 16, 1903:

“The present unsatisfactory arrangements make it necessary for me to give a great deal of personal attention to the work which would not be required with better equipment.” Again, Dr. Smith says: “That the equipment is unsatisfactory we all know, otherwise there would be no reason for legislation.” Again, Dr. Smith says: “No one officially connected with the work has claimed that the board had a model plant, or a plant at all.” Again, Dr. Smith says: “No one would welcome more than I a model plant which represented the simplicity as well as the high standards of our State, and to which all interested strangers would be welcomed.” How can we reconcile these statements with his statement to the Committee on Public Health “that the stable was quite good enough”?

To those who are interested in what Massachusetts is doing, Dr. Smith replies, “that the antitoxin plant is still in the experimental stage, and there is nothing to be imitated, at present.”

President Eliot of Harvard College testified before the Committee of Public Health that there was no test for antitoxin and vaccine virus, and said, “We don't know enough to do that yet, gentlemen.” Dr. Smith says: “The druggist in the case of antitoxin must appeal to the State Board of Health to make the test for strength or sterility, and this body must, therefore, be prepared to maintain standards for such a purpose.” Dr. Smith, speaking of the honesty of the antitoxin, said “that it could only be ascertained by the prolonged inspection and special tests.”

Dr. Smith told me that the serum prepared at the Bussey Institute was tested by comparison with samples sent from Germany that had been approved by the German Government. How can this happen if there is no test, as President Eliot states? If there is no test for antitoxin, how can the board, authorized by Act of Congress, July 1, 1902, to go into effect Aug. 21, 1903, collect samples of antitoxin in the open market and test them as provided for by that act?

These represent but a few of the many inconsistent statements made by the petitioners or their friends all through this contest.

To summarize the evidence on the part of the petitioners—

(1) Mr. Lawrence, counsel for the petitioners, states that Dr. Walcott and Dr. Abbott both were not satisfied with the present condition of affairs at the Bussey Institute.

(2) Dr. Smith in an article in the BOSTON MEDICAL AND SURGICAL JOURNAL of April 16, 1903, states: “That

¹ A reply to Dr. Theobald Smith's letter, April 16, 1903.

the equipment is unsatisfactory, we all know; otherwise there would be no reason for legislation."

(3) Again, Dr. Smith says: "No one officially connected with the work has claimed that the board had a model plant or a plant at all."

(4) Dr. Smith again says: "No one would welcome more than I a model plant which represented the simplicity as well as the high standards of our State, and to which all interested strangers would be welcomed."

(5) Dr. F. L. Morse of Somerville, said to be an officer of the State Board of Health, is quoted in the *Boston Advertiser* of March 12, 1903, as saying: "A good deal of what Mr. Bartlet said [about Bussey Institute plant] is true. That is precisely why the State Board of Health is asking for a thoroughly modern outfit now."

(6) Mr. Bartlet says (see *Boston Transcript*, April 2, 1903): "They know that things at the Bussey Institute are not in the condition that they should be. The Bussey Institute plant is a disgrace to the State." Observe how they all seem to agree with me, that affairs at the Bussey Institute are unsatisfactory, and yet find fault when I criticise the same. That it is of great importance that the bleeding should take place under perfect aseptic conditions, I still contend, and in this I am supported by two biologists of fully as high a standing as Dr. Smith.

The manufacturers agree to furnish a perfectly satisfactory antitoxin and vacciner virus, made under perfectly aseptic conditions and vaccinating all tests prescribed by the Board of Health for one half the price that it would cost the State to maintain a proper plant and make these products. Under these conditions these products would be supplied to the physicians of the State as now at no additional cost to them.

I am pleased to learn that mats are now to be found in the Bussey Institute building, and hope soon to hear that the Herculean effort has been made to turn the hose on to the Augean halls of biological research free from "commercialism" where the horses are kept.

Mr. Lawrence, counsel for the petitioners, remarked that "I went out there with a critical eye;" that disposes of one eye. Dr. Smith declares in this article that I have a "peculiar psychological squint;" and that disposes of the other eye. Handicapped by such an ophthalmic malformation, you must concede in the short space of fifteen or thirty minutes spent at the Bussey Institute plant, that I did remarkably well to see so much. It is fortunate for the petitioners that I did not stay a week, as Dr. Smith suggested that I should have done, for had I done so, no one could have foretold the disastrous conditions that I might have brought to light.

In conclusion, allow me to add that:

You may excuse or deny the filth as you will,
These two dirty stables still stand on the hill.

Very truly yours,

WM. W. BARTLET, PH.G.

"PEYRONIE'S DISEASE—STRABISME DU PENIS."

PHILADELPHIA, April 24, 1903.

MR. EDITOR: I fear J. W. W., Jr., of Pittsburg, Pa., has been listening to many valuable "over the Scotch and soda" clinics of one of the distinguished members of our profession, and has unconsciously become guilty of plagiarism, palming off another's erudition for his own (see *JOURNAL*, Feb. 26, 1903, p. 245). The earmarks of plagiarism are: (I) the title (I have heard S and S" lectures with such title). (II) "Codger," (III) "Yard," (IV) Hutchinson's Archives (see a visit to the Hutchinson's County Home by etc., etc.), (V) *Dictionnaire Encyclopedique* (none such in Pittsburg). Is it possible, like everything else that is good from Pittsburg, it is a "steal"?

Moreover, no one in Pittsburg would ever think of writing a sentimental letter of such character on Valentine's Day. There is too much iron in his soul.

Finally, I find by Polk's that Dr. Ricord lives in Baltimore.

Regretting this further "gold from salt water" tempt to "take in" the Yankees,

I am,

E. T. D., JR.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, APRIL 18, 1903.

| CITIES. | Population Estimated, 1903. | Reported deaths in each. | Deaths under five years. | Percentage of deaths from | | | | |

| Southbridge . . . | 11,268 | — | — | — | — | — | — | — |
| Watertown . . . | 11,077 | 2 | — | — | — | — | — | — |
| Plymouth . . . | 10,730 | — | — | — | — | — | — | — |

Deaths reported, 3,607; under five years of age, 1,033; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 890, consumption 446, acute lung diseases 643, scarlet fever 54, whooping cough 44, cerebrospinal meningitis 8, smallpox 11, erysipelas 11, measles 32, typhoid fever 64, diarrheal diseases 102, diphtheria and croup 89.

From whooping cough, New York 4, Chicago 10, Philadelphia 10, Pittsburg 2, Providence 5, Boston 4, Springfield 2, and Lynn, Lawrence, Brockton, Haverhill, Quincy, Chicopee and Melrose 1 each. From erysipelas, Chicago 2, Philadelphia 1, Baltimore 2, Pittsburg 1, Providence 1, Boston 4. From smallpox, New York 1, Chicago 2, Philadelphia 1, Pittsburg 7.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending April 4 the death-rate was 15.08. Deaths reported, 4,578; acute diseases of the respiratory organs (London) 238, whooping cough 132, diphtheria 58, measles 141, smallpox 13, scarlet fever 39.

The death-rate ranged from 2.7 in Hornsey to 26.8 in Sunderland; London 15.7, West Ham 13.5, Brighton 9.6, Portsmouth 11.0, Southampton 10.9, Plymouth 18.6, Bristol 14.2, Birmingham 15.6, Leicester 13.7, Nottingham 17.4, Bolton 15.9, Manchester 19.1, Salford 18.6, Bradford 15.8, Leeds 14.0, Hull 19.4, Newcastle-on-Tyne 18.5, Cardiff 15.7, Rhondda 17.4, Liverpool 21.1, Handsworth 3.6, Stockton-on-Tees 13.0.

METEOROLOGICAL RECORD.

For the week ending April 18, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

| DATE | Barometer. | | Thermometer. | | Relative humidity. | | Direction of wind. | | Velocity of wind. | | Weather | | Rainfall in inches. | | |

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING APRIL 25, 1903.

T. H. STREETS, medical director. Detached from the Naval Laboratory, New York, and to duty at the Naval Hospital, Philadelphia, Pa.

G. E. H. HARMON, medical inspector. Ordered to the Naval Laboratory, New York.

J. STEPP, assistant surgeon. Ordered to the Naval Hospital, Portsmouth, N. H.

J. B. PARKER, medical director. Detached from the Naval Hospital, Philadelphia, and ordered home to wait orders.

H. H. HAAS, passed assistant surgeon. Detached from the Naval Hospital, Portsmouth, N. H., and granted sick leave for four months.

J. D. GATEWOOD, surgeon. Detached from the "Lancaster" and ordered to the "Yankee."

SOCIETY NOTICES.

CENSORS' MEETING SUFFOLK DISTRICT MEDICAL SOCIETY. — The Censors of the Suffolk District Medical Society will meet for the examination of candidates at the Medical Library, No. 8 The Fenway, on Thursday, May 14, 1903, at 2 o'clock. Candidates should make personal application to the Secretary and present their medical diploma before the examination.

F. J. COTTON, Secretary.

AMERICAN LARYNGOLOGICAL, RHINOLOGICAL AND OTOLOGICAL SOCIETY. — The ninth annual meeting of the American Laryngological, Rhinological and Otolological Society, Lexington, Ky., April 30, May 1 and 2, 1903. The sessions will be held in the Merrie Lodge Building. The profession is cordially invited to attend.

WENDELL C. PHILLIPS, M.D., Secretary.

40 West 47th Street, New York.

BOSTON MEDICAL LIBRARY. MEDICAL MEETING. — The regular meeting will be held in the John Ware Hall, Medical Library Building, The Fenway, on Monday, May 4, 1903, at 8.15 P.M. sharp.

Program: "The Pathology and Etiology of Smallpox." Statement by the President. Dr. Ralph L. Thompson, "The Bacteriolytic Complement Content of the Blood Serum in Variola;" Dr. E. E. Tyzzer, "Experimental Studies in Vaccinia;" Dr. William T. Councilman, "The Skin Lesions in Variola."

ARTHUR K. STONE, M.D., Secretary.

543 Boylston Street.

RECENT DEATHS.

FRANKLIN A. SHERMAN, M.D., of Ballston Spa, N. Y., died on April 22, aged seventy-four years. He was born in Castleton, Vt., and was a grandson of Dr. John A. Woodward, a physician of great repute in the early part of the last century. One of his children, Dr. Frank J. Sherman, is a medical practitioner in Ballston.

RAYMOND W. SHATTUCK, M.D., of New York, died on April 20, of pneumonia, at the age of thirty-one years. He was a native of New York City, and a graduate of the College of Physicians and Surgeons. At the time of his death Dr. Shattuck was serving as a school inspector of the Health Department.

WILLIAM HOLBROOK, M.D., M.M.S.S., died in Palmer, April 27, 1903, aged seventy-nine years.

RESIGNATION.

DR. ROBERT F. WEIR and DR. GEORGE M. TUTTLE have resigned their professorships in the College of Physicians and Surgeons of Columbia College. The reason given for the resignations is that they feel unable to undertake the extra amount of work which the proposed new curriculum for next year will entail.

BOOKS AND PAMPHLETS RECEIVED.

Uterine and Tubal Gestation, a Study of the Embedding and Development of the Human Ovum, the Early Growth of the Embryo, and the Development of the Syncytium and Placental Gland. By Samuel Wyllis Bandler, M.D. Illustrated. New York: William Wood & Co. 1903.

Bacteria in Daily Life. By Mrs. Percy Frankland. New York and Bombay: Longmans, Green & Co. 1903.

Nothnagel's Practice. Diseases of the Liver, Pancreas and Suprarenal Capsules. By Leopold Oser, M.D.; Edmund Neusser, M.D.; Heinrich Quincke, M.D., and G. Hoppe-Seyler, M.D. Edited, with additions, by Reginald H. Fitz, M.D., and Frederick A. Packard, M.D. Authorized translation from the German, under the Editorial Supervision of Alfred Stengel, M.D. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

Nothnagel's Practice. Diseases of the Stomach. By Franz Riegel. Edited, with additions, by Charles G. Stockton, M.D. Authorized translation from the German, under the Editorial Supervision of Alfred Stengel, M.D. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

Surgical Emergencies. The Surgery of the Head. By Bayard Holmes, B.S., M.D. Illustrated. New York: D. Appleton & Co. 1903.

Practical Physiology. By A. P. Beddard, M.A., M.D.; Leonard Hill, M.B., F.R.S.; J. S. Edkins, M.A., M.B.; J. J. R. Macleod, M.B., and M. S. Pembrey, M.A., M.D. Illustrated. New York: Edward Arnold, London, agent for Longmans, Green & Co. 1902.

The Mycology of the Mouth, a Text-Book of Oral Bacteria. By Kenneth Weldon Goadby, D.P.H. (Camb.), L.R.C.P., M.R.C.S., L.D.S., Eng. Illustrated. London, New York and Bombay: Longmans, Green & Co. 1903.

Clinical Treatises on the Pathology and Therapy of Disorders of Metabolism and Nutrition. By Prof. Dr. Carl von Noorden. Authorized American Edition, translated under the direction of Boardman Reed, M.D. Part III. New York: E. B. Treat & Co. 1903.

Conservatism in the Treatment of Acute Mastoiditis. By Sargent F. Snow, M.D., Syracuse, N. Y. Reprint. 1903.

Addresses.

PRESIDENT'S ADDRESS: MEDICAL EDUCATION IN THE UNITED STATES.¹

BY FRANK BILLINGS, M.S., M.D., CHICAGO.

ONE of the chief objects of the organization of the American Medical Association was the elevation of the standard of medical education in the United States. In the president's address the father of the association, Dr. N. S. Davis, stated that "the purpose of the organization was the improvement of our system of medical education and the direct advancement of medical science and practice."² That medical education in that day was defective, as recognized by the founders of the association, is shown by the report of the Committee on Medical Education in the year 1850. The committee said in part as follows: "Medical education is defective because there are too many medical schools; the teachers are too few; there are too many students. The quantity of medicine taught is too limited; the quality too superficial, and the mode of bestowal of the honors of medicine too profuse and too unrestricted."

For many years the association showed its interest in, and attempted to influence, the elevation of the standard of medical education through a committee on medical education. The Transactions of the association of the earlier years show many reports of this committee, which display much thought and effort on the part of the Association to improve the status of medical education at that period of time. James R. Wood, as chairman of the committee, in the year 1858, recommended that the various medical colleges of America be requested to send delegates to a convention of medical colleges, to consider the matter of medical education. This movement finally resulted in the formation of the Association of American Medical Colleges, which thereafter represented, to a degree at least, the American Medical Association in its efforts to improve medical education. Later the Southern Medical College Association was formed. Together these associations represent about 80% of the regular medical schools of the country, and these colleges have, in a general way at least, fulfilled the minimum requirements prescribed by the rules of the associations in regard to the preliminary education of students, the length of the college course, and the character of the curriculum.

About twenty-five years ago the Illinois State Board of Health, through the splendid efforts of Dr. J. H. Rauch, its secretary, made a report on the number and character of the medical schools of the country. This board adopted a minimum of requirements of medical schools as a necessary step toward the recognition of their diplomas by the State Board of Health of Illinois. This minimum requirement of the State Board of Health was gradually increased from time to time, with the result that many of the medical schools were obliged to raise the standard of medical education to enable their graduates to obtain licenses to practice in Illi-

nois. Other states followed Illinois in requirements for better methods of medical education, with the result that the standard of education in the country was very much improved.

MEDICAL SCHOOLS OF THE COUNTRY.

In the earlier days of our country the need of physicians was met by the organization of medical schools which were, as a rule, proprietary in character. These schools attempted the education of physicians on the then existing conditions of medicine by teaching in a didactic way the principles and theories of medicine and surgery. The branches usually taught at that time consisted of anatomy, physiology, chemistry, materia medica, obstetrics, the practice of medicine and of surgery. But little opportunity was offered in the great majority of the schools for extensive, practical teaching in anatomy or chemistry, and but a moderate amount of clinical work in the so-called practical chairs. The course of medicine in the college consisted of two annual sessions of four or five months. The course was not graded. The student attended all the lectures and clinics taught during his first year, and the second year was a repetition of the first. This class of schools was rapidly increased in the course of time. The chief reasons therefor were the fact that it was recognized that a connection with a medical school was profitable, directly and indirectly. The prestige which the teacher enjoyed among the graduates and the laity brought him a remunerative consultation and private practice. In most of the states it was easy to incorporate and obtain a charter for a medical college. It cost comparatively little to conduct and maintain the institution. Lecture rooms were obtained at trifling cost. The dissecting room was not worthy of the name of a laboratory, and the chief expense in maintaining it was the cost of dissecting material, which was usually deficient in quantity and poor in quality. Medical schools were organized all over the country, without reference to the needs of the people. Medical education was prostituted. To obtain a sufficient number of students many institutions showed a most degraded disregard of the moral and mental qualifications of the matriculates. The income of the school was wholly derived from the tuition of students, and no applicant was turned away who had the cash with which to pay his way. To add to the facility of obtaining a medical college course, there were organized in some cities evening schools, the hours of college attendance occurring from seven to nine or ten o'clock at night. These sundown institutions enabled the clerk, the street-car conductor, the janitor and others employed during the day to obtain a medical degree.

In spite of the general tendency to increase the facility by which a medical degree could be obtained, there was a force at work to improve the methods of medical education. A few older medical colleges and an occasional new one set the standard high in relation to the existing status of medicine. There were earnest, forceful medical men in some of the schools who fought for a higher standard for matriculation and graduation.

The medical college associations exerted a splendid moral influence for good, and the state boards in all the more advanced states have, by mandatory

¹ Delivered at the fifty-fourth annual session of the American Medical Association, at New Orleans, May 3-8, 1903. Published by courtesy of Journal of the Association.

² Transactions A. M. A., vol. xvi, 1865.

legislation, compelled the colleges to raise the requirements in reference to the preliminary education, the length of the annual session, the time of medical college study, the character of the curriculum, etc. As a result, the status of medical college education has been very much improved in the last twenty, and chiefly in the last ten, years. But, improved as it is, there are evils which menace us, the chief of which still are too many medical schools, too many students, and inadequate facilities for the proper teaching of medicine.

The improvement in medical college requirements has increased the cost of the maintenance of the medical college to a degree that it is no longer a profitable financial venture. There can be no dividends. Indeed, the proprietors of the private institution must often make up a deficiency in the annual budget. In spite of this fact, medical colleges have continued to increase steadily.

In 1877 there were 65 medical schools in the United States; in 1882 this number had increased to 89, and 1901-02 to 156. The enrollment of students and the number of graduates have also increased, in spite of the fact that the requirements for matriculation and graduation have been increased. In 1882³ there were 14,934 matriculates, and this number was increased in 1901 to 26,417, and in 1902 to 27,501, an increase of about 100% in twenty years.

The number of graduates in 1882 was 4,115; in 1901, 5,444; in 1902, 5,002, an increase of about 25% in twenty years. If, in 1850, there were too many medical schools and too many students, what can we say of the condition today?

It has been estimated that there is an average of one physician to 600 of the population of the United States at the present time. The natural increase in the population of the country, and the deaths in the ranks of the profession, make room each year for about 3,000 physicians, based on the proportion of one physician to 600 of the population. With 5,000 or more graduates each year, a surplus of 2,000 physicians is thrown on the profession, overcrowding it, and steadily reducing the opportunities of those already in the profession to acquire a livelihood. The evil of an overcrowded profession is a sufficient cause of complaint, but the cause thereof is the important point for us to consider, and, if possible, remove. To correct the evil, the ease and facility with which a medical degree may be secured in this country must be diminished. As before stated, there are now 156 medical schools in this country. Of these, 30 are sectarian, and 136 are so-called regular schools. Fifty-eight are medical departments of universities, of which 24 are state institutions. The relation of the medical school to the university in most instances is a nominal one only. In but few of them is the control of the faculty, or the finances of the medical department, vested in the university proper. In a very few of them the sciences fundamental to medicine are taught in the university. In the majority of these schools these departments are duplicated in the medical department, and are taught by members of the medical faculty. In most instances, too, the teachers of the fundamental branches are physicians who devote but a part of their time to teaching.

They teach without salary, or for a nominal one only. Their remuneration is obtained by private practice, to which they must devote their best energies, to the detriment of their value as teachers. The clinical department of these schools is, in most instances, wholly inadequate. The majority of such schools depend on the general hospitals, situated near them, for the privilege of the use of clinical material. Necessarily, these clinical advantages have great limitations, inasmuch as they cannot be fully controlled for the purpose of proper bedside teaching, or for scientific investigation. Some of the medical schools which are connected with state universities are situated in small cities where it is impossible to command an adequate amount or variety of clinical material. The connection with a university, which many of the schools enjoy, is, therefore, almost valueless in a pedagogic sense. The majority do not differ materially from the private or proprietary schools in their value as teaching institutions. Ninety-eight of the medical schools in the country are private corporations, organized, maintained, and, as a rule, owned by the faculty. If, in earlier years, these institutions were sources of direct financial profit to the owners, they have ceased to be so now—at least most of them. The evolution of medicine has made it necessary to extend the laboratory method of teaching. As these schools attempt to teach the whole curriculum, the erection, equipment and maintenance of the necessary laboratories have so increased the cost of conducting the schools that they are usually no longer self-supporting. The temptation is in such schools to conduct them on a plane which shall just comply with the minimum requirements of the various state bodies, which regulate medical practice in the several states. They are maintained ostensibly to teach medicine, but in reality for the prestige which a professorship affords the teacher in his private and consultation practice. Proprietary schools depend on general hospitals and dispensaries for clinical material. What was said of the status of clinical teaching of the medical departments of the universities is true also of the proprietary college. These schools cannot hope to improve their present standards. The majority attempt to maintain laboratories and other expensive means of teaching which a modern medical education demands. But in how many are the laboratories worthy of the name? What kind and variety of instruments and apparatus do they afford? Are their teachers of the sciences of the fundamentals of medicine capable? They cannot hope for better conditions, because the time when a student's tuition will pay the school for his instruction, if he is properly taught, will never return. Medical education of the future must be based on the status of medical science. That basis is recognized now, but is attempted in the great majority of our medical institutions in a very superficial way.

SCIENTIFIC MEDICINE.

The great and important discoveries of Pasteur and the practical methods devised by Koch in bacteriology marked a new era in medicine. Before the facts made clear by these discoveries, the hypotheses and theories of other days have dis-

³ The Journ. A. M. A., vol. xxxix, No. 10, p. 574.

appeared. Our knowledge of man and the lower animals and of the diseases and evils which afflict them has been revolutionized within the last twenty years. The advance in medical knowledge has been greater in that period than in all preceding time. Medicine now embraces many more subjects, chiefly fundamental ones, than were known twenty years ago. Formerly a very superficial knowledge of a few isolated facts in general chemistry and human physiology and a memorized knowledge of human anatomy and of *materia medica* enabled the student to learn the practice of the art of medicine and surgery. Now, the problems which confront the clinician and investigator in medicine and surgery compel him to have a good and working knowledge of general, physical and physiological chemistry, of general biology, bacteriology, pathology, physiology, embryology, pharmacology, histology and anatomy. The physician who has not a practical knowledge of these fundamental subjects cannot clearly understand the methods of others engaged in scientific investigation, nor can he rationally utilize the discoveries of others in his work. Medicine today is applied science. If we utilize the knowledge of today in an attempt to cure and prevent disease, it must also be an experimental science. No one can practically apply or rationally experiment with what he does not know. The fundamental studies of medicine, must, therefore, be acquired by all who desire to successfully apply them as sciences. The successful experimental application of these sciences has given us within ten years a knowledge of the method by which the invading bacteria affect the host, and has likewise developed a principle of wide application as a preventive and cure of certain diseases by the use of antitoxic sera. It has confirmed the principle of preventive inoculation, accidentally discovered by Jenner, and has enabled us to apply the principle in other diseases than smallpox. It has enabled us to know the methods of transmission of certain infectious diseases, and to know how to stamp out scourges like yellow fever, the plague and malaria.

Through the evolution of Listerism, it has enabled the surgeon to invade every region of the animal body, and to save scores of lives formerly doomed to death. The freedom with which the surgeon may now operate has not only saved lives, but, indirectly, the knowledge of disease processes so studied during life has taught us many new facts in symptomatology, and has cleared away many fallacies concerning pathologic processes. It has given us many new methods of clinical study, and furnished data from the blood, the spinal fluid, the exudates, the sputa, the sweat, the feces and urine, which enable us to recognize disease much more readily than before.

Much has been accomplished by experimental medicine in a comparatively brief period of time; there are vast fields to which the method has not been applied. With most of us, our present methods of clinical observation enable us to do little more than name the disease. In the vast majority of the infectious diseases we are helpless to apply a specific cure. Drugs, with the exception of quinin in malaria, and mercury in syphilis, are valueless as cures. The prevention and cure of

most of the infectious diseases is a problem which scientific medicine must solve. What is true of the infectious diseases is also true of the affliction of mankind due to chemical influences within the body. We know but little of diabetes, of the primary blood diseases, or of the various degenerative processes of age and disease. We hopefully look to chemistry to reveal to us the cause of these and other conditions. Experimental medicine must be the means of removing the ignorance which still embraces so many of the maladies which afflict mankind. Not every student, nor every physician, can become an experimenter in applied medicine. Nevertheless, every physician must be so educated that he may intelligently apply the knowledge furnished him by experimental medicine in the cure of such diseases as can be cured. He will no longer juggle with the life of his patient by an attempt to cure with drugs or otherwise, where no help is possible.

METHODS OF MEDICAL EDUCATION.

The phenomenal evolution of medicine has multiplied the subjects of medical study. The character of these sciences requires that they shall be taught by the laboratory method. The laboratory method, too, has been adopted as the chief method of instruction in anatomy, pharmacology and chemistry, formerly almost wholly taught in medical schools by didactic lectures. The laboratory method, while necessary to the proper and practical instruction of the student, involves an expense which is appalling when compared with the methods of teaching formerly practiced in all schools, and still adhered to in many medical schools. The method is expensive, inasmuch as it involves more extensive buildings, much expensive apparatus and an increase of the teaching force. The instruction must be individual or to small groups of laboratory workers, and this involves also an extension of the time of instruction. A physician engaged in private practice cannot possess and retain the general and technical knowledge necessary to enable him to teach one of the fundamental sciences properly, nor can he devote an adequate amount of time to it. The teachers of these fundamentals must be investigators in the province of their respective sciences. They must give their whole time to the instruction of students and to original investigation. The thoroughness and accuracy of the training of the special senses, and in experimenting, which a student will receive from such teachers in properly-equipped laboratories, will make him keen in intellect and sound in judgment. His desire for knowledge will be stimulated by the atmosphere of his surroundings, and will awaken in him a consciousness that through him and his work the knowledge of the world will be increased and humanity benefited thereby. But teachers of this character must be paid salaries quite as large as the remuneration of professors in the departments of arts, literature and science. The salaries of such professors and of the corps of assistants which the laboratory method implies make the cost of the university or college far beyond the income which could be derived from the tuition of students. I believe it has been estimated that the laboratory method of instruction, now followed by all first-

class institutions of learning, costs annually from four hundred dollars to five hundred dollars per student. But, great as the cost seems, it must be conceded that the present status of medicine demands the thorough instruction of students in these fundamental studies. It matters not whether his future may be that of a teacher or a practitioner of medicine. In either event, he must apply his knowledge of the fundamental sciences to his work, and the result will depend on the thoroughness of his education.

APPLIED MEDICINE AND SURGERY.

To enable the student to utilize the knowledge of a thorough training in anatomy, physiology, chemistry, pharmacology, physiologic and physical chemistry, embryology, neurology and pathology, he should be afforded facilities of equal rank in clinical medicine and surgery. To supply the student with proper clinical facilities involves several important features. Special hospitals, which would be absolutely under the control of the medical school, would be necessary. The hospital should be constructed with a definite idea of teaching students and of making researches into the nature, causes and treatment of disease, as well as to care for a definite number of patients. Hospitals for general medicine, surgery and obstetrics would be essential. Such hospitals, with laboratories and equipped with instruments, apparatus and library, would cost for their building and maintenance a very large sum of money. With such hospitals it would be necessary to choose the professors of medicine, of surgery and of obstetrics, with competent assistants, of the same type as the teacher of the fundamental sciences. They should give their whole time to the work of teaching and to original research in the hospital. They should be men who have proved their scientific fitness for the important positions, by the contributions they have made to medical knowledge. They should rank with and receive the pay given to professors of important departments in arts, philosophy and science. When so paid, they would be free to expend all their energy to teaching, and to experimental medicine—a career which would enable one to be of the greatest possible service to mankind. No life's work could be fuller or of greater self-satisfaction, and surely none would be more honorable. From these teachers and investigators the student would obtain instruction of the same systematic methods of accurate observation and investigation which were employed in the fundamental branches. He would receive thorough, conscientious drill in the fundamental methods of examination of patients, and his knowledge of the fundamental sciences would be constantly applied in this work. The trained clinical teachers would direct the student in thorough, careful observation in the wards and at the operating table, would collect data to be submitted to experimental tests, and would conscientiously carry out the experiments in the laboratories of the hospital.

The brilliant discoveries which have made our knowledge of the cause and means of transmission of many of the infectious diseases have been chiefly due to the introduction of the experimental method of investigation. Teachers and investigators of

the type mentioned will have the opportunity to make equally important discoveries in the broad field of the unknown in medicine. They will train students in the methods of research work and constantly increase the number of investigators in the domain of medicine. And there is need for such men. We may give the great practitioners who have taught clinical medicine their due meed of credit for their excellent, painstaking, unselfish efforts as teachers. They have added to the sum total of our clinical data, have utilized the knowledge of the pathologist and the physiologist in diagnosis, and have tested and judged the worth of therapeutic aids in the treatment of disease. But as teachers they have not made students investigators or experimenters. Not one of the recent great discoveries in medicine has been made by such a man. He has used as clinical material hundreds of cases of pneumonia, rheumatic fever, tuberculosis and chronic diseases by the score; his experience has taught him to recognize these diseases, even when the clinical manifestations are obscure, but he is no more successful, than when he began to practice, in saving the life of the patient with pneumonia, in preventing endocarditis in rheumatism, in curing tuberculosis, or in checking the advance of a chronic hepatitis. It is time, therefore, that the clinical teacher should have the knowledge necessary to carry on experimental investigation, with hospital facilities for the work, that the profession may become purged of the shame of helplessness in curing so many of the common diseases of mankind.

The patients who will be received in these hospitals will be fortunate. They will receive the most painstaking examination and study, and the experiments made on animals in the laboratory will benefit the patients directly, inasmuch as more rational therapeutic measures will be applied in cases so investigated. In addition to the clinical teachers who will devote all their time to teaching and research work in the special hospitals, there will be quite as much need for the clinical teacher who is in private practice in the general hospitals. Under his direction the student may himself investigate a hospital or ambulatory case, and undertake the care of the patient. His rich and varied experience in hospital and private practice will enable him to round out the student's college education. He will impart to the student a better idea of medicine as a whole. He will co-ordinate and arrange the isolated facts of clinical and laboratory investigation, and give them their true and relative value. He will teach the student the art of medicine; he will teach him that human sympathy and encouragement of the sick and dying are a part of his duty as a physician.

It would be most practical to make the clinical work of the third year a clinical drill and experimental course, given in the special hospitals, and assign the students of the fourth year to the general hospitals and to the clinical teachers who are in private practice. All the general hospitals and dispensaries controlled by the medical schools could be utilized in the fourth year for this purpose, and afford the student an abundance of clinical material and the benefit of the experience of many clinical teachers. Many of the assistants in the special hospitals, of the third year course, would doubtless

engage ultimately in private practice, and would, because of their scientific attainments, make excellent clinical teachers in the fourth year. A medical school conducted on the high plane advocated must necessarily be under the control of a university. Such a medical school would cost an enormous amount of money, and this can be commanded only by the trustees of a university of the highest order. That the money for the purpose of establishing and maintaining university medical schools with research hospitals and university extension clinical courses will be forthcoming cannot be doubted. The world is awake to the great discoveries recently made in medicine. The wealthy men of this country have had their interest aroused as never before in reference to the possibilities and benefits which medical investigation will give to mankind. They now recognize that they and all posterity will be benefited by every new fact discovered in medicine, and that physicians thoroughly and scientifically trained are necessary to conserve the health of the people.

Three years ago Prof. W. W. Keen, in his address as president, deplored the fact that medical schools received relatively little aid in the form of endowments as compared with universities and colleges of philosophy, art and theology. Since that time several millions of dollars have been given for medical education and scientific research. The signs of the times point to a brighter future of medicine in America.

EDUCATION PRELIMINARY TO MEDICAL STUDY.

The subject of the educational requirements for matriculation in medical schools has been discussed at many meetings of this association in its earlier years, and later by the college associations, by the American Academy of Medicine and by the various state boards of health.

The requirements were at first lamentably low, and the efforts of the Committee on Education of the American Medical Association and of the college associations had but little effect, because they possessed no legal power to control the schools.

The influence of the various boards of health of several states, notably Illinois, was more marked, inasmuch as these state boards possessed a mandatory power. The colleges were forced to adopt the minimum educational requirements of the state boards of health, if their diplomas were to be recognized by the respective state boards.

These moral and legal influences to improve the preliminary requirements were almost nullified by the practice of a majority of the medical schools in admitting students whose educational status was examined into and judged by a committee of the college faculty.

This practice is still followed by a majority of the medical schools, and results in the admission of many students who are unable to fulfil the prescribed requirements. As a subterfuge, students are often matriculated conditioned in one or even several subjects. Then the student and the faculty committee forget all about the subject, and the student completes his course, goes into practice, and dies with the conditions still undischarged.

The present requirements of the college associations and of the various state medical examining

boards and state boards of health amount, on the average, to a high-school education. The curricula and length of course of the high schools of the different states, and even in the same state, differ very substantially. However, if the medical schools now in existence would honestly require as a minimum education the diploma of a high school, without regard to the rank, it would be a marked advance over the present requirements as practiced by most schools.

We must admit, too, that there are medical schools of such a low educational grade that they have no right to demand of their matriculates as much even as a common school education. This fact that low-grade medical colleges exist is one of the most satisfactory explanations of the difficulty encountered in elevating the standard of preliminary requirements.

To get at the root of the matter, the medical college must be brought up to the proper educational standard, and then, and then only, can be made a proper preliminary educational requirement.

UNIVERSITY MEDICAL COLLEGE.

The present status of medical science requires and demands a university medical college course. By university medical college is meant a medical school which is directly connected with and a part of a university; the university fixing the requirements and controlling the admission of students to the medical department. The method of teaching both the fundamental and the clinical branches is on the principles outlined above. To properly prepare for such a course the student should have, as a minimum preparation, at least two years of study in a good college or university. The requirements to enter a good college or university would ensure a sufficient knowledge of the ordinary school branches and also Latin or Greek. During the two years' course in college his time would be well spent in the study of English, French, German, mathematics, history, philosophy, physics, chemistry, general and organic, and qualitative analysis, comparative anatomy and general biology. The amount of time to be devoted to each of these subjects would be the same as that of students of general science, as arranged in all college curricula, with the exception of a much more thorough course in chemistry, biology, physics and comparative anatomy.

So prepared, the medical matriculate would be able to grasp all the intricacies of the subjects of the fundamental branches of medicine. With the addition of the full medical college course, as outlined above, his education would be equal in culture to that of the graduate in arts and philosophy. At the same time it would be practical, and especially fit him for his work as a scientific investigator or practitioner, or for both.

With the medical profession so educated, a physician would be, in truth, a member of a learned profession. From an educational point of view, he would rank as an equal with the scholar in philosophy, law and theology. As a man he would be recognized as the greatest benefactor of mankind.

With the establishment of university medical schools the first two years of work in the medical school will consist of courses in pure science.

Then, doubtless, all universities will adopt the plan which two or three universities have already put in practice; that is, that the student who completes the first two years of the science course of a university, or at a college of good standing, may enter the sophomore year of the university and take the first two years' work in medicine as the sophomore and senior years of the bachelor's course, when he would receive the degree of S.B. The student who completes the three years of the arts or philosophy course at a university, during which he should take a large amount of work in physics, chemistry and biology, could then enter the medical college, and after two years receive the degree of A.B. or Ph.B. After two years spent in the clinical school he would receive the degree of M.D.

This telescoping of the literary and medical courses affords the advantage of an economy of time, while it does not in any way lessen the value of the result to the student. In the one case the student secures the degrees of S.B. and M.D. after about six years of study, and in the other the degrees of A.B., or Ph.B., and the degree of M.D. at the end of seven years' study.

THE OUTLOOK OF MEDICAL EDUCATION IN THE UNITED STATES.

Medical education must advance to its proper level if it complies with the present status of the medical sciences and the demands which continued evolution in medicine promises.

What does this imply? It means that the private—the proprietary—medical school which is conducted for commercial reasons must go. Acknowledge, as we must, the great value which the best of these schools have been to the profession and to the country, all such schools have lived past the time when they can be of value. The continuation of these institutions henceforth will be harmful. They cannot command the money to build, equip and maintain the laboratories and hospitals which a proper and adequate medical education demands. In the past their graduates have furnished the many great and influential medical and surgical clinicians of this country. In former days a graduate poorly prepared has been able, by indefatigable labor and post-graduate work, to place himself in the front rank as a clinical physician and surgeon.

Today medical science demands primary instruction to fit a man as an investigator and scientific physician. If not properly educated he cannot grasp the great problems which medicine presents today as he did the more simple clinical facts which comprised the art of medicine and surgery a few years ago. In the future medicine must be taught in the large universities of the country and in the state universities which are situated in or near large cities, where an abundance of clinical material may be commanded.

The state university and the college which desires to teach medicine, and is so situated that it cannot command clinical material, should confine itself to teaching the sciences fundamental to medicine. These should be taught as pure sciences, and should be included in the course for the degree of S.B. A college or state university ambitious to teach the medical sciences can do so without great cost. To

attempt to teach applied medicine without proper and adequate hospitals, and with an insufficient number of patients, would be irrational, nor can they command the necessary funds with which to do it. From such colleges and state universities the students could go to the larger institutions which are able to furnish the proper facilities for teaching applied medicine and surgery.

The general hospitals of many of the cities, now used by proprietary schools, could be utilized as clinical schools for both undergraduate and post-graduate teaching, conducted by the clinical teachers in the existing proprietary schools. Indeed, these hospitals could be utilized as university extension clinical courses. Necessarily they would have to be under the control and direction of a university medical school.

How many schools may be necessary to educate the number of doctors of medicine required annually in the United States? The question one cannot answer, but it is safe to say that twenty-five hundred graduates annually will fully supply the demand. This would imply about ten thousand to twelve thousand matriculates. A minimum number of twenty-five and a maximum number of thirty-five medical schools should offer sufficient facilities to educate ten thousand students. The various state universities and the colleges which offer adequate science courses would educate a great number of students in the fundamental branches, or in the first two years of the medical course.

MEDICAL RECIPROCITY BETWEEN THE STATES OF THE UNION.

The low requirements of some medical colleges, and the want of uniformity in the requirements for a license to practice in the different states, has resulted in a condition which entails much hardship on a physician who desires to remove from one and to engage in practice in another state. The rules of most state boards of medical examination and of health are so stringent that a physician or surgeon of years of experience and of acknowledged skill and education, and the specialist who may be renowned in his field of work, are obliged, like the recent graduate, to take an examination in all of the branches of medicine and surgery in order to secure a license to practice in the state of his adoption.

To correct this evil it has been suggested by a member of the American Medical Association, and concurred in by others, that a national board of medical examiners be organized; that the board hold examinations at different seasons of the year in the various large cities, and that the diploma so obtained shall be recognized as a license to practice in any one or all of the states and territories. The measure suggested seems to be practical and feasible.

In addition to this plan, it remains to be said that the degree granted by the future university medical school will be undoubtedly recognized as an evidence of fitness to practice in any state in the Union. When we shall have a less number of schools and annual graduates, the various states may safely and rationally become more liberal and discriminating in the conduct of their office.

THE INFLUENCE OF THE AMERICAN MEDICAL ASSOCIATION.

The American Medical Association should maintain its interest in the elevation of the standard of medical education, one of the chief reasons of its organization. Its influence in former years was principally moral. This was of considerable value, for the reason chiefly of the high ideals of the founders and first members of the association, who advocated and fought for a high standard of medical education. In the future its influence should be many fold that of the past, for with the reorganization of the profession the better methods of conducting its affairs, the increased and probably very large membership, and its great medical journal, should wield a great influence for good.

As the direct agent by which the American Medical Association may exert its influence in the elevation and control of medical education, the Committee on Medical Colleges and Medical Education should be made permanent and should be given adequate power and sufficient annual appropriation to make its work effective.

This association should, therefore, stand for, and should use its whole power to improve, medical education in this country. It is said that we never exceed our ideals in practice, and that if we lower our ideals our conduct sinks to a lower level.

The American Medical Association should take as its ideal and standard of medical education the university medical college, with all the name implies in regard to the fundamental medical sciences, and to the clinical branches. It should use its influence to drive out of existence those proprietary medical schools, which are conducted solely as money-making institutions. These measures cannot be accomplished at once; but medical science demands it, the profession demand it, the people demand it, and look to the American Medical Association as the chief influence which shall accomplish this end.

CANCER AND IMMUNITY.¹

BY A. F. JONAS, M.D., OMAHA, NEB.,

Chairman of the Surgical Section.

ON such occasions as this we take great pleasure in recalling the past and dwell with great delight on the achievements along the lines that have most engaged our attention. We, as surgeons, especially those whose professional activity began in the pre-antiseptic period, review the successive changes from that period of expectancy to the present period of aseptic accuracy with the greatest satisfaction. No one can fully appreciate the present status of surgery who is not personally familiar with the period when wound complications were the rule and when faith was pinned on the belief in "laudable pus." . . .

Surgical advance in the future will not consist so much in the radical changes in operative technique as in improvement in diagnosis and diagnostic aids. Many of our diagnostic formulæ are even now undergoing complete changes, and the future will lead us to a precision in the recognition of disease

that we little dream of now. The early recognition of malignant disease is a problem of future development, especially malignancy affecting the internal organs. With our present aids it is impossible to recognize internal cancers sufficiently early to do a radical operation. Our only course at the present is an exploratory incision as soon as reasonable grounds for malignancy exist.

The field that seems full of promise and gives us hopes for great expectations in the future is that of immunity and immunization. It now seems that many tissue changes will be solved along these lines. From our present viewpoint the question of immunity seems to tower above and overshadow all others. . . . The two greatest problems of the future, cancer and immunity, shall engage our attention today. Malignant disease seems to be on the increase. We stand so helpless in its presence when fully developed that we exert our feeble energies and grasp eagerly for any fact that seems to offer new light for its better understanding. It will be our effort at this time to as briefly as possible review the more important facts known regarding the etiology of cancer and then, after making clear to ourselves the revelations thus far made in the recent studies of immunity, determine if possible what relations, if any, exist between the two.

These considerations were prompted by personal observations made in a number of cases of undoubted malignancy that indicated the probable infectiousness of cancer. It is well known to us all that the infectiousness of most infectious diseases was first determined clinically and that the clinical observations were later determined and confirmed microscopically and experimentally. . . .

The term cancer, so commonly employed, refers to growths made up chiefly of epithelial cells. There is really no good reason why the term cancer should be limited to epithelial growths. Cancer signifies "crab." It was originally used to signify malignancy and meant connective tissue growths as well as those of epithelial origin. For our purpose at this time we will limit the term cancer to epithelial neoplasms and we will confine these considerations to its etiologic factors.

The mystery of its origin seems as deep almost as in the days when cellular pathology was unknown. No problem in pathology has received more thought and speculation, no subject has had bestowed on it more earnest effort and unremitting toil. Regarding etiologic evidence we must confess that we have only a mass of negative proof. When observers believed that they had found the specific organisms, scores of workers in the same field soon demonstrated their error. So, today, we can only say that the evidence which shows what we do not know of the cause of cancer is voluminous, and we must admit that we know little of its etiology.

We know something of its cell characteristics. We know that malignant disease is essentially a cell proliferation that has, biologically, many features that are opposed to the physiological tissues in which they take their origin. We find an atypical life history in the cancer cells. The nucleus divides in an asymmetrical way. We note that unusual karyokinetic figures in the nucleus are usual in new growths, pointing to changes in the cellular life his-

¹ Oration in surgery, delivered at the fifty-fourth annual meeting of the American Medical Association, held at New Orleans, May 5-1903.

tory. Regarding carcinoma, certain bodies have been demonstrated, believed by some to be parasites, having some causal relation to the cell changes.

It is a well-established fact that the nucleus perpetuates the nature and function of the cell, and any change in the nucleus changes the cell in its function and process of division. According to W. V. Shaw, "The growth of cancer cells is then to be looked on as an effort of reproduction in damaged tissue, the incidence of the damage falling on the nuclear structures."²

This statement is based on observations made by him in connection with experiments on free swimming larvæ which developed from the stimulation of ova of certain lowly organized animals, causing a proliferation of cells. The ova had not been fertilized by spermatozoa. Adult organisms were not developed, but larvæ capable of independent life. These results were obtained by stimulating the ova with strychnia and by mechanical movements of the ova. This cell growth was compared to growth of tissue in partially damaged structures. Shaw believes that such damage alters the nature of these cell structures so that the vegetative functions of the cell run riot and the cells become parasitic toward the organism in which the growth is taking place. This view seems to find support in those connective tissue growths that develop in tissues that have sustained a trauma and in which the sarcoma develops; or in epithelial growths that form on surfaces that have been subject to prolonged irritation, as exemplified by the chimney-sweep's and paraffin-worker's cancer forming on an old chronic dermatitis; or a cancer forming on the site of a prolonged irritation by the smoker's pipe-stem on the lower lip. We have seen many times that cancer develops in epithelial tissue that has been subjected to irritation for a long time, usually extending over a period of years. We have long recognized irritation to be at least one of the causative factors. Just what metabolic disturbances take place, and what the underlying causes are, is not yet clear. That cancer is infectious has been proven by many clinical observations. This has been shown by Eberth, who collected twenty-two cases where cancer was transmitted from lip to lip, tongue and palate. Behla reported eight instances of death from malignant growths in physicians and surgeons who were inoculated from tumors, and four instances of apparent human infection from cancerous animals, dog and hen. He also alludes to a cancer epidemic among the white mice in the Pathological Institute at Freiburg as evidence of the contagiousness of cancer (Hektoen). Roswell Park believes that, for New York State at least, cancer is increasing at an alarming rate.

Attempts have been made to show that cancer is endemic, peculiar to certain localities. Behla cites cases of Behrens, who found in a village ten deaths out of thirty-eight to be due to cancer. Pfeiffer, Powers and Friesinger maintain that in certain houses (cancer houses) and marshy districts in the vicinity of ditches and streams containing sluggish water, especially if the stagnant and polluted water were used for watering garden vegetables and for drinking purposes, cancer is relatively frequent

(Hektoen). This would point rather to a microphyte than to a microzoon as the etiologic factor.

Since infection of living tissue is believed in every instance to be due to bacterial invasion, naturally bacteriologists directed their attention toward the discovery of a specific germ. Very soon we had a long list to enumerate. Plimmer of London examined in six years 1,298 carcinomata, and in 1,130 he believed that he found parasitic bodies. Sjöbring laid much stress on cell inclusions. Russell described his fuchsin bodies which were spherical or oval. L. Pfeiffer of Weimar published several monographs on the protozoa as a cause of cancer. Eisen brought out his *Canceri Amebe*. Korotneff believed that he had found an organism which he termed *Rhopalocephalus carcinomatosus*. Bosr found and described an organism that he called *Myxosporidia coccidia*. Gaylord of Buffalo described at great length bodies that he believed bore an etiologic relation to cancer. Sanfelice of the University of Cagliari emphasized the etiologic importance of bodies that he named *Saccharomyces neoformans*. A very large number of other publications on this subject made their appearance, none of which differed in any essential point from those bodies just mentioned.

While the presence of the aforesaid bodies described by the different observers can be demonstrated and are present in a large proportion of the cases of cancer, all the requirements necessary to prove them to be the organisms solely responsible for cancer have not been fulfilled. The requirements necessary are: (1) the organism must be isolated; (2) a cancer must be produced when the organism is introduced into another body; (3) the organism must be recovered from the cancer produced. It has been shown that, while the first requirement has only apparently been fulfilled, the second has been, in a number of cases, seemingly produced. More careful investigations have proven that the experimental growths were not cancer. The third requirement has not been fulfilled.

All of the work mentioned above was carefully reviewed in all its details by the cancer committee, who, in their second annual report to the surgical department of the Harvard Medical School, showed conclusively that the bodies described by the various investigators under different names were not cancer nor the cause of cancer. I can do no better than to quote in full the results of their labors. They bear the marks of painstaking and conscientious work. The conclusions of the Harvard Cancer Committee were written by Edward H. Nichols and were as follows:

It has been claimed by the adherents of the theory of the parasitic origin of cancer that

(1) A proliferation of epithelial cells analogous to the lesions seen in cancerous tumors can be produced by certain well-known protozoa (nodules caused by the *Coccidium oviforme*).

(2) Certain skin lesions characterized by epithelial cell proliferation are due to the action of a so-called protozoon (*Molluscum contagiosum*).

(3) Blastomycetes are constantly present in human cancers and are the cause of the lesion.

(4) By experimental inoculation of animals with blastomycetes, true epithelial or cancerous nodules can be produced.

(5) Finally, the well-known endocellular bodies seen

²The Lancet, Sept. 20, 1902.

the protoplasm of cancer cells have a definite morphology, are parasites and the cause of cancer.

It has been the object of the investigators, the results of whose work appear in the preceding pages, to study each of these questions. As a result of the lines of work pursued by them under the direction of the Cancer Commission during the past year, it is concluded that:

(1) The lesion produced by the *Coccidium oviforme* is essentially a process of chronic inflammation and is not analogous to the lesion seen in cancer.

(2) The lesion of *Molluscum contagiosum* is characterized by certain changes in the epidermis, is not due to the action of a protozoon and is not analogous to cancer.

(3) The so-called "blastomycetes" (*saccharomycetes*) *Sanfelice* and *Plimmer* are *torulæ*.

(4) The lesions produced by these "blastomycetes" (*torulæ*) are, essentially, nodules of peculiar granulation tissue, are not cancerous, nor, in any sense, true tumors.

(5) Blastomycetes are not constantly present in human cancers.

(6) The peculiar bodies seen in the protoplasm of a cancer cell are not parasites, nor the cause of the lesion, but probably are, in part, at least, atypical stages of the process of secretion by glandular epithelium.

It is clear that in the present status of the etiology of cancer, bacteriologically considered, the case has not been proven. But it does not follow that it will not be shown that cancer is due to a specific and well-defined organism. It may be an organism so minute as not to have been brought within the range of the microscope. It is possible that no stains have yet been found that possess the requisite affinity for its complex molecular constitution. The necessary artificial medium for its cultivation remains for some future investigator to solve. Be that what it may, since the clinical features give strong evidence of the infectiousness of cancer, the search must and will be continued along the same lines.

In this search for a specific contagium, cellular metabolism must not be forgotten. Its consideration and study is perhaps more important than the isolation of a specific germ. It cannot be denied that the more exact our knowledge of cytomorphosis becomes the clearer will be our understanding of cell proliferation. It has long been understood that there must be certain stimuli that cause cell growth and certain inhibitors that limit cell development and exercise control in accordance with the requirements of the tissues. Certain other influences bring about a disturbance of the normal equilibrium between the stimuli and the inhibitors. It is evident that the exact nature of the stimuli, the inhibitors and the disturbers must be ascertained. This involves a study of the cell constituents and the fluids that surround it. As we see, it is a question of chemistry. . . .

What has malignant disease to do with immunity? The entire subject of immunity has to do with infection. It has to do with its nature, mode of action and control. Has cancer any characteristics that pertain to infection? Bacteriologically we have found none. Clinically we have a mass of evidence that would seem to place cancer among the infectious diseases.

In order to have a clear understanding of the modern conception of immunity, it is necessary to review, as briefly as possible and in barest outlines, without comment, the most important features of

our present knowledge of the subject. Much material that may seem essential to a complete elucidation of this great and important subject had to be eliminated on account of the limited scope of this dissertation.

More than a century ago we find that John Hunter was familiar with some antiseptic properties of the blood. He found that a small amount of putrefying material could be added to a given quantity of fresh blood without producing putrefaction. Consequently he advanced his doctrine of "the living principle of the blood." This, as an observation, was almost forgotten and its import was not fully realized until Nuttall, in 1888, began his systematic work, in Flügge's laboratory, studying the antibacterial properties of the body fluids, especially the blood serum.

The greatest impetus to the study of immunity was given by Metschnikoff in calling attention to the participation of the leucocytes and other cells in the process of infection, establishing his well-known theory of phagocytosis. His views are so well understood that we need only to call attention to them at this time.

Following Nuttall, Pfeiffer discovered, in 1894, "The extracellular disintegration and solution of cholera spirilla in the peritoneal cavity of immunized guinea pigs."

The greatest attention and interest was aroused by Behring's great discovery of antitoxic immunity. Bacteriologists at once endeavored to elucidate by elaborate researches the exact way in which immunity was established. Chief among these was Ehrlich. It was soon shown, however, that immunity in most bacterial infections did not depend, in the main, on the antitoxic principle.

Pfeiffer's phenomenon afforded a starting point from which Metschnikoff, Bordet, Ehrlich and Morgenroth began their labors and brought forth a series of discoveries that have been epoch-making.

A series of antibodies were differentiated and classified as antitoxins, antienzymes, cytotoxins, agglutinins, precipitins and coagulins. Antibodies were in turn produced by these, with the exception of the antitoxins.

It was determined that to every cellular group of an animal species there appears to correspond a specific cytotoxin. These various toxins have been termed leucotoxin, neurotoxin, spermotoxin, nephrotoxin, thyrotoxin, etc.

These antibodies have been divided into two groups; first, the antitoxins, which are single bodies; second, the cytolytins, whose antagonistic effects require the co-operation of two bodies.

Of these two bodies, the one which actually destroys the foreign cells is normally present in the cells or fluid of the organism; but it seems incapable of action without the intermediation of a body which is distinguished from it by a greater resistance to heat. The two elements composing cytolytins exist quite independently of each other, so that one may be present without the other, or be artificially removed without affecting the other.

To demonstrate the mode of action and constitution of the specific antibodies, Ehrlich has propounded the theory of receptors or side-chains. The atomic grouping of the toxin molecule, which affects the union with antitoxin as well as with a

particular cell, he has designated as haptophore groups.

In view of the fact that certain molecule groups of the living protoplasm favor the taking up of certain poisons, he has termed them receptors. According to his theory of antitoxic formation, after the introduction of toxins the receptors are produced in excess and finally are thrown off into the blood as useless ballast. The free circulating receptors are the antitoxins, termed amboceptors, intermediary bodies. The action of antitoxins is explained thus: They take charge of the haptophore groups of the toxin molecules and prevent them from approaching the receptors of the tissues.³ There are as many receptors as there are toxins, while almost every day new ones are discovered.

Behring gives the most exact and brief definition of Ehrlich's antitoxin theory: "The same substance which, when incorporated in the cells of the living body, is the prerequisite and condition for an intoxication, becomes the means of cure when it exists in the circulating blood." Every antiserum protects only against substances through which it becomes immunized. Every antiamboceptor protects only against its particular amboceptor.

Ehrlich and Morgenroth found, in experiments with goat's blood, thirteen different new lysins which represent so many receptors. "The receptors are in the cells, not for the purpose of linking poisons to the cells, but to seize certain foodstuffs, particularly proteids, and the toxins, bacterial and other foreign cellular substances, if capable of inducing the immunizing reaction, chance to have the requisite combining affinities for the receptors."

The living body possesses bactericidal and cytolytic substances which may protect it by destruction of invaders or may injure it by destruction of its own cells, according to the mates with which they are paired.

In considering the physiological mechanism of the cells we find that they are designed, primarily, for the assimilation of food, and, secondarily, to meet pathologic conditions, the production of antitoxins, cytolysins and other similar bodies. The receptors are in the cells for the purpose of taking up foodstuffs, chiefly proteids. The toxins and bacterial cellular substances have combining affinities for the food receptors, if they are capable of inducing an immunizing reaction.

In producing immunization against bacteria, it is the intermediary body (amboceptor) which is generated. It has been found that these antibodies have a specific relation to the substances which caused their formation, as has been shown by the injection of a specific serum into an animal at certain intervals, of toxins, against which an antitoxin is desired.

The specific nature of these antibodies is further shown in their application to serum diagnosis, as shown by the Widal agglutination test for typhoid fever and the serum test in the diagnosis of *B. dysenteriae* Shiga, an organism shown to be the cause of acute dysenteries by Flexner, Vedder and Duval.

When Roux and Yersin discovered diphtheria antitoxin, and Ehrlich the origin and mode of action of antitoxin, a lasting foundation for the study

of immunity was laid. It was positively shown that "soluble toxins enter, as assimilable substances, into combination with constituents of the body cells for which they have an affinity," and are enabled to produce immunity or to exert toxic effects.

The expectations that we should soon be enabled to solve all questions regarding the action of toxins after the discovery of soluble bacterial toxins have only partly been realized, especially regarding the action of the pyogenic micrococci, which concerns us most as surgeons.

However fruitless, hitherto, the practical results regarding toxins of many pathogenic and especially pyogenic organisms, the principle has been established, and it is only a question of method and time when all body toxins and their antitoxins shall be definitely known.

Pfeiffer directed his attention to the bacteria and found substances, toxins, in cholera spirilla, which became free only after the bacteria were dead and which were termed intracellular poisons. This was a most important step in advance, but we must acknowledge that we know as yet very little about the action and nature of intracellular bacterial poisons.

It is interesting to note from the result of Flexner's experiments with venom that its action on red blood corpuscles, leucocytes and nerve cells is like that of duplex cytotoxins, which depend on the combination of intermediary bodies contained in the venom on one hand, with corresponding complements in the cells or fluids acted on. This is shown by the addition of venoms to fresh blood, which brings about the quick destruction of the red blood corpuscles. If the fresh blood has been washed with an isotonic salt solution, so as to remove all the complement, we find that the corpuscles are not dissolved, but agglutinated. It seems that the venom serves chiefly to bring "into necessary relations with constituents of the body cells poisons we already harbor or may generate, but which are harmless without the intervention of intermediary bodies."

Flexner and Noguchi have shown that the leucotoxic, the neurotoxic and other cytotoxic properties of venom depend on combinations of venom, intermediary bodies with complements contained in the cells poisoned by venom, or in the fluids bathing these cells, indicating that the snake venom contains only a part of the complete poison.

Flexner and Noguchi also demonstrated that hemorrhages in various tissues of the body resulting from poisoning from certain venoms is due to the presence in venom of a cytotoxin which has the power to dissolve endothelial cells, which they termed endotheliolysin (hemorrhagin). It causes extravasation of blood through its direct solvent action on capillary endothelium.

The hemolysins have been most extensively studied because of their great pathologic significance, and it has been found that many bacteria have hemolytic power. The secondary anemias, so constant in streptococcus infections, in pneumonia, typhoid fever and other diseases, afford a most striking example.

Normal blood serum contains antihemolysins which protect red blood cells from bacterial hemo-

³ Ehrlich: *Schlussfolgerungen*, p. 176.

lytic agents. Associated with hemolysins are bacterial hemagglutinins, possessing the power to clump red corpuscles.⁴

Heuter and Klebs believed that thrombi were due to the coalescing of red blood corpuscles. Welch calls attention to hyaline thrombi formed by agglutinated red corpuscles. White corpuscles are agglutinated by certain bacteria and also by pus cells.

What is urgently needed is a separation of these poisons and a determination of their source, constitution, mode of action and degree of specificity.

It will not be out of place here to allude to the studies made of the ductless glands, because of their supposed bearing on immunity. Sajous urges that the adrenal extractives have a decided affinity for oxygen, offering a key to tissue respiration and to the functions of all other organs now classed as the ductless glands. It has been found that the red corpuscles are not the only carriers of oxygen, but that the blood plasma contains and distributes this gas. Schmiedeberg, Jacquet, Claud Bernard and others demonstrated the existence of an oxidation ferment in the plasma, and these bodies are now entertained as an oxygen-laden secretion. This secretion is believed to permeate nearly all the body elements. The blood also contains a fibrinogen body which combines in certain quantities with fixed portions of the plasma's oxygen. The changes in the temperature of the blood were traced to variations in the amount of the fibrinogen in the plasma. The adrenals have been shown to be connected with the anterior pituitary body by various sympathetic ganglia. The anterior pituitary body is regarded as the governing center of the adrenal system. Over-activity of this body increases the adrenal secretion, consequently oxidation, therefore vital resistance. Depression of the activity of the pituitary body causes decreased supply of oxygen, consequently depressed vital processes.

The thyroid secretion, thyreoidin, has been shown to sustain the efficiency of the pituitary body. Excessive thyreoidin production stimulates the pituitary body and produces exophthalmic goiter. Deficient thyreoidin production leads to myxedema. The adrenals, the pituitary body and the thyroid gland constitute the adrenal system. According to this line of research, it is believed that toxins act directly on the adrenal system, and, by decreasing or increasing its secretion, decrease or increase the oxidation process. Certain toxalbumins and many drugs stimulate the adrenal secretory powers to a certain limit, and, when exhibited in excessive doses, depress or arrest the functions of this system.

The posterior pituitary body has been shown by Berkley, Andriezen and others to be the chief functional center of the nervous system. It is the center for such emotions as shock, excitement, etc. It governs all organic functions through the nervous system. The secretions of the pancreas and spleen, according to Schiff, and later by Herzen, unite and change trypsinogen into trypsin, a solvent for the albuminous bodies in the pancreatic juice. This ferment performs an important part in immunizing processes, in that it destroys toxalbumins.

Viewing these labors in the light of Ehrlich's researches, the oxidizing substance represents the

amboceptor; the spleno-pancreatic internal secretion, trypsin, represents his complement. To produce a proteolytic action of trypsin, fibrinogen and the oxidizing substances are required. These views are somewhat at variance with those commonly accepted, but are of sufficient importance to deserve consideration in this connection.

From the foregoing it would seem that the doctrine of phagocytosis plays an unimportant rôle. But we find that the French, or phagocytic school, at the head of which is Metschnikoff, recognizes the full significance of acquired immunity and the cytolytic principles represented by the co-operative action of intermediary bodies and complements. The German, or humoral school, led by Ehrlich, recognizes the leucocytes to the fullest extent.

The chief difference between the French and the German schools consists in the belief by the advocates of phagocytosis that the complements reside in the leucocytes, whereas the adherents of the humoral school believe that they exist in the blood plasma.

While, in what has here preceded, we have been concerned in the consideration of chemical problems, we must not overlook the fact that behind all is a governing force which resides in the central nervous system.

The practical outcome of these studies has been found in the production of antitoxic sera, some of which have been proven to have a definite and exact effect under certain conditions. We find these sera divided into two principal groups: (1) those that have an antibacterial action, and (2) those that have a purely antitoxic action. Of all the sera the diphtheritic is best known. According to Welch the mortality of diphtheria has been reduced from 40% to 15% by its use.

Antitetanus serum has been disappointing. Reports coming to us from different sources are conflicting, the mortality ranging from 0% to 70% from practically the same methods, which consist in administering the serum by the subcutaneous, intracerebral and the spinal methods. Antityphoid serum has failed to fulfill expectations even more than antitetanus serum. The antistreptococcus serum of Marmorek, while it seems to have exerted a specific effect in purely streptococcic infections, appears to exert no influence in the presence of mixed infections. The antipneumococcic serum has not yet emerged from the experimental stage. Nothing can be said of its effects. The anti-plague serum of Haffkine and Yersin demonstrated that, as a preventive, it reduced the number of cases to one-twentieth and the mortality in a given number of cases was reduced from 33% to 13% (Calmette). The antitubercle serum has been shown to have a specific effect on tuberculous tissue, but remains powerless in the presence of mixed infections. The antivenom serum has been demonstrated to have a positive usefulness in certain snake bites. Calmette's antivenin has been proven to be of undoubted use in leprosy.⁵

Many other sera have been described, but their usefulness thus far has been shown to be of an uncertain nature. Consequently we will leave them out of consideration at this time.

⁵ F. A. Packard and Robert M. Wilson: Amer. Journ. of the Med. Sc., December, 1900.

⁴ Heuter-Klebs, p. 731.

When we pass in review all that is positively known in relation to the question of immunity, we cannot deny that some of the principles underlying this great question have, in a measure at least, been revealed. The evidence is conclusive that "the same substance which, when incorporated in the cells of the living body, is the pre-requisite and condition for an intoxication, becomes the means of cure when it exists in the circulating fluid."⁶

Ehrlich, in his investigations of diphtheria toxins, demonstrated "that soluble toxins enter as assimilable substances into direct combination with constituents of the body cells for which they have an affinity, and only thereby are enabled to bring about immunity or to exert toxic effects." Further, in connection with Metschnikoff, Bordet, Morgenroth and Ehrlich, it is shown that "the organism possesses a power to produce substances specifically antagonistic to all sorts of foreign cells, cellular products and derivatives. The substances capable of inducing this immunizing reaction appear to be mainly of an assimilable, albuminous nature, or at least intimately associated with such material."

The principle of toxins and antitoxins has become as firmly established as any other in medicine or surgery. We have noted that antitoxins from pure cultures have a certain affinity for and possess immunizing power in specific infections, but fail in the presence of mixed infections. We see at once that failure to immunize does not violate the principle, but that the method of application has been at fault. We know that diphtheria toxin has a specific effect for the products of the Klebs-Loeffler bacillus, and that it controls and cures in the presence of these, but fails when there is an admixture of other forms of infection. This is shown by the 15% mortality which still exists. We have noted that antistreptococcus, tubercular and plague sera have a specific and a decided effect in pure infections, but that they fail in the presence of other specific germs. We observe with satisfaction the certainty of the action of a given antitoxin in its union with the toxin from which it was produced. It at once becomes apparent that, in the presence of several toxins or a mixed infection, it will require several antitoxic substances, a combination of antitoxic sera, or a serum containing different kinds of amboceptors, so combined as to meet and unite with the several toxins in a given case. Coley endeavored to meet such indications by combining streptococcus and Bacillus prodigiosus sera in treating inoperable sarcoma.

These observations presage a revolution in therapeutics, which perforce means a refinement in diagnosis beside which what we do now will scarcely bear comparison.

The inferences to be drawn from the foregoing indicate that the future work will be biochemic. It appears that the solution of cell metamorphosis, as it is observed in pathologic conditions, will be in the field of chemistry. Ehrlich's theory of the side-chains has given us a working hypothesis almost as practical as the atomic theory when applied to chemistry. It is not an idle dream to believe that the revelations of the future will not only consist in a complete exposition of cells and body fluids, or a

perfect understanding of the governing brain centers, but may extend to the life principle itself, although life itself may and will ever belong to the unknowable.

Our chief interest, however, will always center in the cell and its governing influence. Just what influences are responsible for normal cell division may never be known. But it is within the bounds of human possibility to know what influences may be responsible for atypical and excessive cell growth. Excessive cell growth, both in the leucocytes and connective tissue cells in acute infections, we can assume to be due to toxins that are in excess of the amboceptors. The existence of cytolytins and anti-cytolysins is now undisputed. The one destroys, the other protects the cells. We have noted that the chief function of a receptor molecule is to combine with nutrient molecules a metabolic, a chemical process. The birth and growth of the cell is restricted within certain limitations and is regulated by chemical law. Now the problem depends on our ability to ascertain the exact influence that carries cell division beyond its normal bounds and causes excessive cell growth as we observe it in malignant new growths. That the process is one of localized excessive nutrition is apparent. The localities of predilection are frequently at points where the cellular elements are exposed to frequent insults, where the tissues are damaged, establishing a *locus minoris resistentiæ*, as, for example, in the mouth, gastro-intestinal tract and the female reproductive organs. A point of least resistance, damaged tissue, if you please, always offers a soil for bacterial invasion. Cancer very often develops in tissues that have long been irritated, no doubt liberating a complement that unites with a specific infection when introduced under proper conditions. Such is not always the case, however. In fact, we know that in the majority of cases tissues that sustain irritations and almost constant traumatism for many years never become malignant. The simple traumatism does not develop cancer. A specific toxin must be introduced, probably also an intermediary body to complete the side-chain, which increases karyokinetic energy. We have noted in our studies of immunity that the life or death of the cell depends on its intra- and extra-cellular composition, so we may say that the whole process, whether it relates to normal or excessive cell growth, is chemical.

An objection may be urged at this point, which consists of the fact that the propositions of immunization thus far considered affect groups of cells extending over a wide range, that is, the vascular, the muscular and the glandular or cerebrospinal systems. It has been shown that cancer is always at the outset, and often throughout its entire course, absolutely a local disease. It would not seem rational to attempt immunization of the entire system against a strictly local disturbance. We will naturally turn our hope toward a method that will enable us to effect local immunization.

That local immunization is possible has been demonstrated by P. Römer in the following convincing abrinimmunization experiment. As is well known, abrin, which is the toxalbumin of the jequirity bean, will produce a severe conjunctivitis in animals and men. Ehrlich had demonstrated that rabbits' conjunctivæ became immune after the in-

⁶ Welch: Behring's Definition of Ehrlich's Theory Concerning Antitoxin.

stillation of abrin. Römer instilled into the right eye of the rabbit weak abrin solutions, the dosage being rapidly increased until immunization was produced. In three weeks the rabbit was killed. It was then shown that if the right conjunctiva, which had undergone severe inflammation, were rubbed and macerated with a certain amount of abrin and injected into a healthy animal, it had no effect. But, if the conjunctiva of the left eye, which had received no instillation, were rubbed and macerated with abrin and injected into an animal, death always followed. Römer concluded from this observation that in conjunctival immunizations a part of the autotoxin existed in the conjunctiva itself. A local antitoxin was produced.

It would seem that these results established definitely the principle of local immunization in indifferent tissues. These observations have an important bearing on the adaptation of these cells to local affections. That local affections of various forms, or general affections with local manifestations, can be best managed by the local introduction of exceedingly small doses of the specific remedy, was shown by Professor Bouchard before a recent meeting of the Egyptian Congress. He found that articular rheumatism disappeared after the injection *in situ* of small doses of salicylic acid, in some cases only half a grain. We must conclude that local cell metabolism can be influenced by local rather than by general diffusion. The inhibition of excessive cell growth must be accomplished in the same way.

It would seem, then, that the cancer question must be solved along the lines of chemistry. Since we know that contagious or infectious energy does not depend on the bacterium itself, but on its products, which are purely chemical, it would seem that it matters little whether the specific parasite is found or not. Since the cancer germ has thus far successfully eluded the most vigilant search, it becomes more and more evident that in the field of chemistry will be found the solution for our problem.

It will be difficult to rid ourselves of time-honored views. Purely theoretical speculation, like the hypothesis of cell proliferation from inclusions of embryonal matrices according to Cohnheim, must give way to the demands of modern science that insist on actual observations and practical demonstrations.

Now, then, will it be unreasonable to hope that when protoplasmic changes are thoroughly understood and when the body sera have given up their secrets and the influences that govern cell growth, we may also find the antibodies which will inhibit cell multiplication beyond natural bounds?

The studies in the field of immunity have, as yet, only assumed the proportions of the initiatory stage. A vast unexplored wilderness lies before us. The pioneers have begun their work well. They have outfitted themselves in a manner that will, in the near future, enable them to throw unexpected light on the pathway of their conquest of discovery. They are only on the verge of this vast domain. What lies beyond the borders we can no more foretell than could Boyer know that in twenty-four years after his death we should have anesthesia and that in fifty years the world would have antiseptic surgery. And yet, in the light of our present knowledge, the hope, amounting to a conviction,

arises in us that even in our lifetime, if we are spared a few years more, we will have an exact bio-dynamic and bio-chemic science that will make diagnosis accurate and precise, and one that will enable us to treat and control all infections with an exactness not now possible. While the surgeon is now constantly encroaching on the field of the internist, the time is not far distant when the physician may not only reclaim his own, but with it that large group of neoplasms known as malignant growths that from time immemorial has been the exclusive property of the surgeon.

BRACHIAL PARALYSIS, POST-NARCOTIC.

BY F. J. COTTON, M.D., AND S. W. ALLEN, M.D., BOSTON.

THE following instances of post-anesthetic paralysis are presented because the writers believe that such cases should be put on record. Few of the cases are reported, and, as a consequence, the risk we run of having this accident occur is not always appreciated. It is apparently always avoidable, if the etherizer knows the risk and has it in mind.

CASE I. Miss P., aged twenty-five, healthy, moderately robust; etherized May 6, 1901, for an operation on the hip. The anesthesia lasted a little over two hours. During etherization both arms were raised: the left forearm was on the pillow above the patient's head (but not under any tension); the right arm lay abducted with the elbow flexed, only the supinated hand resting on the pillow. The position was practically unchanged during the whole operation.

After an uneventful recovery from ether, the patient showed a practically total paralysis of both arms.

On the right there was entire loss of power in the extensors of the hand and wrist and of all muscles supplied by the ulnar nerve. There was fair power of flexion in the fingers and good ability to pronate the forearm, but supination was lost. The triceps was paralyzed, the biceps and brachialis anticus only partly so. There was entire loss of power over the deltoid and supra- and infra-spinatus muscles.

On the left, flexion of the fingers was very weak. Neither pronation nor supination could be carried out — nor, in fact, any motions below the shoulder, save weak elbow flexion and flexion of the fingers. The deltoid retained better power than on the right, and the posterior rotators of the shoulder seemed to be intact.

There was no pain and no sensory disturbance beyond a very moderate hypoesthesia and paraesthesia mainly in the ulnar distribution on the left. The tendon reflexes could not be obtained. There were no changes in the pupils, nor in the width of the palpebral fissures.

Improvement in function began to show itself at three days, with recovery of power in the biceps and triceps on the left side, in the finger flexors on the right. At four days the extensors of the wrist on the left began to show improvement — the muscles of the ulnar supply on the right.

From this time on, improvement was irregular in progress but continuous. At ten days there appeared marked tenderness of the nerves in the axilla and to a less extent along their whole course in the arm. At the same time the muscles of the upper arm became tender. At sixteen days there was some power in all the affected muscles, least in the deltoid and shoulder rotators on the right, in the muscles of the hand and in the wrist extensors on the left. No electrical examination was made. No active treatment was used save for massage.

A month after the operation there remained only a slight weakness, some contracture of the flexor muscles (which rapidly yielded under massage) and some paraesthesia in the ulnar distribution on the left side. This paraesthesia lasted several months, but finally disappeared. When last seen the patient had recovered entirely.

CASE II. Seen by one of the writers in 1893 — the details are quoted from memory. The patient was a young woman of slender physique but healthy; the operation was for acute appendicitis, and was a relatively short one. During etherization both hands were held above the head on the pillow.

On recovery from ether, she was found to have a total paralysis of all muscles of shoulders and arms of both sides.

Feeble power returned to the hands in about ten days, and from this time there was gradual improvement, but a paresis of the shoulder muscles and of the intrinsic hand muscles and some sensory disturbance in the hands persisted for several months. Eventually there was entire recovery.

CASE III. (Seen by one of the writers some time after the accident.) A young man, operated on for appendicitis. His hands were said to have been above his head during the forty-five-minute etherization. After recovery from ether there was practically total paralysis of both arms, but not of the shoulder muscles, with a good deal of sensory disturbance. Partial recovery in a couple of days. A good deal of pain in the forearms persisted for some weeks, and some paraesthesia for about four weeks. Recovery of function was slow, and even up to date he has not recovered quite the normal flexor power of the left hand.

CASE IV. (Seen by one of the writers two weeks after operation.) A middle-aged, robust woman was operated on for an abdominal lesion; during the operation the arms are thought to have been above the head. On recovery she had a total paralysis of both arms. When seen there was still a nearly complete paralysis of the musculospiral supply right and left, with paresis in the supply of median and ulnar on both sides; there was then no involvement of the shoulder muscles; there was hardly a trace remaining of the initial hypoesthesia in the hands. The initial improvement here, as in the other cases, had been within a couple of days or so, after this a slower progress toward recovery.

These cases are typical post-anesthetic paralysis. The writers believe such cases to be much more frequent than the scanty literature would suggest. A cursory search of the literature has yielded only thirty cases of this type. The type we would define as that in which paralysis of a part or the whole of

the brachial plexus has evidently resulted during anesthesia from mechanical causes. We would exclude from consideration the many cases recorded where the paralysis has had a central or reflex origin, or those evidently due to direct pressure on the peripheral nerve trunks from pressure of the body on the arm in lateral postures, from pressure of the edge of a table on the musculospiral nerve, from pressure of leg-holders or the edge of a Trendelenberg table on the peroneal nerves, or from the too efficient application of a tourniquet.

In this list of thirty cases there is a considerable uniformity. The patient is anesthetized with the arms abducted or drawn up above the head, and after recovery from the effects of a prolonged operation it is found that one or both arms are paralyzed. There is little or no pain and relatively slight sensory disturbance. The muscles of the shoulder and arm are affected in varying degree — sometimes all are involved, sometimes the paralysis is of the nerves from the upper roots, sometimes the shoulder muscles are spared and the hand and arm muscles mainly affected. Within a few days there is a beginning return of function, more usually in the hand, then a much slower return of power to the extensors, to the deltoid and the rotators of the shoulder. As the function returns many of the cases present a paralysis approximately of the "Erb type" (deltoid, biceps, brachialis anticus and supinator longus).

In a very few cases (Büdingen) there is involvement of the sympathetic root communicating into the first dorsal nerve, signalized by pupillary and other ocular changes.

The sensory disturbance may rarely be considerable. As a rule it is confined to moderate hypoesthesia and various paraesthesiae of mild type.

Later on soreness of nerve trunks and of muscles may appear. Reflexes are usually normal. Electrical tests rarely show a partial reaction of degeneration or slow contractions — as a rule the reactions are normal. All¹ cases recorded have recovered spontaneously or with the use of electricity, save one case of Mally's, where a paresis of both deltoids remained as a residuum from a total paralysis of both arms. There was some doubt even here whether the persistence of the paresis was not due to a chronic arthritis of both shoulders which appeared in this case.

As a rule the recovery of a fair amount of muscle power occurs within a few weeks, but full recovery may be long in coming.

The type of injury is that associated with peripheral nerve injury from pressure or traction, and in so far as these brachial plexus cases are concerned we need not trouble about the theory of the toxic effects of chloroform or ether, anemia, etc., except in so far as they may represent a favoring condition.

As to the pathological anatomy of these cases there are no data save those furnished by Büdingen's examinations. In one of these no lesions of the plexus were found at autopsy, in the other it is definitely stated that even microscopical examination failed to show any lesions whatever.

¹This statement applies, of course, only to the special class under consideration. Paralysis with central lesions, tourniquet paralysis, etc., associated with anesthesia do not necessarily share this good prognosis.

We are at liberty to assume, as we like, severer lesions in severer cases, but Büdinger's cases were typical clinically, and the latter case at least as severe as any described. It seems fair to infer from his data that we have to do rather with interrupted function than with any definite structural change.

There is no question, from the data, that the position of the arms is the cause of the trouble. There is no case recorded in which the trouble occurred where the arms lay on the chest or at the sides of the body; in all cases where there is a record of the position they were either above the head or at least well abducted. That long-continued stretching upward of the arms may affect the plexus is shown by the rare occurrence of fleeting numbness or paresis, where the arms are so placed in sleep, and, still better, by the cases reported as "*Klimmzug-lähmung*," where repeated passive hanging from gymnastic apparatus sometimes produces a partial paralysis of the Erb type (but including the serratus magnus, and sometimes the levator anguli scapulae and rhomboids), sometimes of rather obstinate character.²

It is easy to see how positions which under ordinary circumstances may give no trouble may readily become exaggerated from the muscle relaxation of ether. With such relaxation and a continuance of the vicious position for one or more hours, it is easy to conceive that harmful pressure or tension may result. Just *how* this happens is not fully determined. There are three possible mechanisms to be considered:

(I) Pressure on the plexus: (a) exerted between the clavicle and the transverse processes of the vertebrae, especially the fifth and sixth; (b) between the clavicle and the first rib.

(II) Tension on the roots or plexus from position of the arm.

(III) Tension from position of the head and neck, the arm being abducted.

The relation of position to the involvement of single roots clinically proves to be of no use in helping determine the manner of damage. Where we find it noted that the arms were, during narcosis, stretched above the head, we find paralysis of all, or practically all, the brachial plexus, in five cases; of upper roots alone, in three cases; of circumflex (deltoid alone), in one case; of lower roots and part of upper roots, in one case.

Where the arms were abducted and not stretched upward, we find paralysis of the whole plexus, one case; of lower roots especially, one case; of upper roots, partly of lower, one case. These results are too inconstant to be conclusive as to detailed lesions.

It would seem that it should be easy to determine these effects by experiment on the cadaver; in fact, it is not so simple: as each investigator has in turn advanced his theory he has always "proved" it by cadaver experiment.

The writers, in their turn, carried out patient observations on a number of partly dissected cadavers, trying to verify the alleged effects of position, especially with regard to the special nerve roots pressed on in special positions.

To our surprise we found it very hard to produce

any considerable tension or pressure on the brachial plexus by any position akin to those occurring clinically. The following results, such as they are, were constant with different cadavers:

With the upper arm abducted to a right angle and supinated and the elbow dropped back, the median, the musculospiral, and especially the ulnar nerve are under some tension, and there is some stretching of the plexus, as a whole, over the first rib and over the head of the humerus.

With the arm above the head, no nerve save the circumflex could be put on the stretch. As for the pressure exerted by the clavicle on the plexus, either against the first rib or against the transverse processes of the vertebrae, it could not definitely be demonstrated in any position that could be compared with those occurring in narcosis. As Guillaume and Duval pointed out, the plexus, when the arm is extended upward, moves into the hollow of the clavicle and is protected. Such pressure as is exerted is between the clavicle and the masses of muscle in the neck over the transverse processes. The plexus is slack, and there is not even a chance of stretching it.

These observations make it clear enough how damage may result with the arm abducted and supinated. As to the damage occurring (as it most often does) from stretching of the arms above the head, they suggest rather than demonstrate an explanation.

It is obvious from the clinical point of view that only in *exceptional* instances does the plexus suffer *any* trauma. It is obvious from the experiments that this trauma is from pressure if the arms are extended upward,³ from tension if the arm is abducted and supinated. Probably the latter cause is less common. This we may assume not only because this is clinically the less commonly noted position in these cases, but because tension must especially affect the ulnar nerve (see experiments), while, in fact, it is in most cases the muscles supplied by the upper roots that suffer.

We would emphasize the following points:

Paralysis of part or all the muscles supplied by the brachial plexus with some sensory involvement is not very uncommon after narcosis, though rarely mentioned.

Its cause is not toxic but mechanical. It occurs only when the arms are long held above the head or lie in abduction—never if they lie flexed on the chest.

The mechanism is a pressure on the nerve roots, probably between the clavicle and the muscles over the transverse processes of the cervical vertebrae, or from stretching over the head of the humerus in abduction.

The trouble is essentially functional without known lesions.

The lost function returns *in part* very early. Total recovery is often long delayed, but apparently is to be counted on.

The possibility of the accident should be impressed on students, on house officers and on all of us.

In view of this risk the arms of a patient under ether should always, where possible, be flexed with the hands on the chest. If other positions are un-

³ Probably ischemia may play a part. Every anesthetist knows how this position checks the radial pulse.

² Schrmann: Deutsche Med. Woch., 1900, xxvi, p. 6.

voidable they should not be continued long without change.

PYRONIN - METHYL GREEN: A BRILLIANT DOUBLE STAIN FOR CELLS AND BACTERIA.

BY WILLIAM F. WHITNEY, M.D., BOSTON.

The staining properties of a combination of pyronin (a basic red aniline) and methyl green were first brought forward by Pappenheim in his work on plasma cells; but he did not emphasize its great general utility, and it is to this especially that I desire to call attention. For the brilliant contrasts which are obtained in specimens stained by it in the simplest way make it of the greatest value for the examination of fresh isolated cells and of smears of sputa, pus and other fluids.

The method of preparation and use is as follows: A 1% solution of pyronin and methyl green¹ in distilled water are made separately, and mixed in the proportion of four parts of the former (red) to one part of the latter (green). The resulting rather opaque, deep purplish fluid will keep for several weeks without precipitating. If, however, only occasional use is required, as in office practice, the solutions are best kept in separate bottles, and a little of the mixture can be quickly made with a dropper.

Cover-glass preparations.—A drop of the fluid to be examined (gonorrheal pus, for example, gives a very brilliant picture) is spread thinly in the usual way and dried; on this a few drops of the color are placed; it is heated for a few seconds and washed off thoroughly with water. The cover glass can then be mounted directly on a slide in a drop of water, or, preferably, after drying, in xylol balsam.

On examination with a high dry, or better with an oil immersion lens, it will be seen that the nuclei of the cells are bluish green, the bodies of the neutrophilic leucocytes are unstained, while those of the lymphocytes, mast cells, endothelial and epithelial cells have varying shades of purple by which they can be readily distinguished from each other. Against all of these any bacteria stand out in sharp contrast by their brilliant red color. The effect of the whole picture is heightened by the transparent background, which is perfectly colorless if the preparation has been properly washed.

This stain does not touch the red corpuscles, and if it is desired to bring them out or use it for the examination of blood, the smear must be treated first either by the Ehrlich heating, ether-alcohol, methyl-alcohol or Zenker-nitric method for fixing the hemoglobin. Then it is to be colored with a 1% aqueous solution of orange G, well washed, and lastly covered with the pyronin-green mixture. In this way the red corpuscles are of a light yellow

color, and reddish granules appear in the orange-colored cytoplasm of the polynuclear leucocytes.

The 1% solution of pyronin can be used alone as a good counter stain after Gram's method by simply allowing it to remain on the decolorized preparation for a minute or two. The bacteria, which have been decolorized, take up the red, and thus come into vivid contrast to those which have retained the original violet.

Fresh preparations.—For the examination of fresh cells (scrapings from tumors, etc.) it is only necessary to add a drop of the mixture to the fluid or to the scrapings suspended in water. After thoroughly stirring about with the point of a needle, a cover glass is placed over the drop. The excess of fluid can be drawn off by placing a bit of filter paper carefully against one edge of the cover glass. After this the cells can be washed by bringing a drop of clear water against the edge opposite to the paper and allowing it to run through in the same way. Nucleus and cell body are stained differently, and the various kinds of cells can be readily distinguished from each other. All the nucleoli are prominent by their deep pyronin staining. The corpora amylacea of the prostate are colored a light brown.

Frozen sections.—A good double staining is given to frozen sections of tissues hardened in formalin, by placing them for a short time in a little of the fluid, and then washing in water. They can be mounted in glycerin, or syrupy levulose, but should be examined at once, as the color diffuses in a short time. Since alcohol extracts the color completely, permanent preparations are very difficult to be obtained. Pappenheim has given a complicated method with resorcin as a mordant, but it has not been a successful one in the hands of others.

In conclusion it should be remembered that if the slides and covers are scrupulously clean, the smears spread thin and evenly, turbid solutions filtered, and the diffused color thoroughly washed out, then the chances of a successful preparation are always greatly increased.

X-LIGHT IN ANTHROPOMETRICAL SIGNALMENT.

BY WILLIAM ROLLINS, BOSTON.

THE time will come when the law will require every person on reaching adult age to be signalized. Meanwhile we know from the researches of Bertillon and others that the anthropometrical department of signalment is the foundation of every valuable method of identifying criminals. Any procedure which will make these measures more exact must be valuable, for already the number of signalments is several hundred thousand in France alone. Every day the chances of making a mistake in identification become greater. The difficulty is not in the first separation, but in the last group, in which the measures are most alike. The ordinary measures taken are—height, length of trunk, reach, length of head, width of head, bizygomatic diameter, length of right ear, length of left foot, length of middle finger, length of left middle finger, length of left forearm. Of these measures it may be said

¹ Grubler's colors, obtained from Ernst Leitz, 411 West Fifty-ninth Street, New York, were used.

that they are of value only when they are accurate. It is evident that if we could take any of these measures with twice the accuracy now possible, we could identify twice as many persons. This we are able to do by the method I have devised—that of making x-light photographs of the bones. I estimate that this method at least doubles the accuracy with which measures of the hand can be taken, and by enabling other measures of the feet, beside the length, to be taken it allows at least four times as many persons to be identified as at present, though the real number will be found to be much greater; for when we consider that x-light not only gives us photographs of the dimensions of the bones but also shows their structure, it is evident for purposes of fine distinction in the final stage of the identification the method is an advance. In cases of bodies burned or decomposed before they are discovered, the method would have some advantages over any that has been proposed. In other cases where only some of the parts of the body are found, as for example a hand or a foot, the method alone might lead to identification. I have designed and constructed apparatus for conducting these x-light photographic anthropometric signalments, and have described them in other papers, as they appeared too technical to interest the readers of a medical journal. I hope, however, the method may interest physicians, as it is a more exact appeal to anatomy as an aid to identification than any yet proposed. Indispensable requisites for making such measures of value are to have the source of x-light at a uniform distance from the photographic plate; to have the plate bear on its face evidence of the direction and distance of the source of x-light and the angle at which the central ray struck. Apparatus for accomplishing these results, to which I have given the name orienter, was illustrated in this journal for 1901 and much more fully in my notes on x-light in the *Electrical Review*. I mention the matter here because the apparatus is important to physicians from a medico-legal point of view when x-light negatives are used in court for evidence.

Clinical Department.

A CASE OF ACUTE OSTEOMYELITIS OF THE CERVICAL SPINE.

BY HENRY S. WARREN, M.D., BOSTON.

From the Orthopedic Clinic of the Carney Hospital.

J. G., a male twenty-three years of age, came to the Orthopedic Out-Patient Department of the Carney Hospital on Jan. 20, 1902, with the following history: Family history negative; personal history that of a perfectly well man up to the present illness.

Five months before entrance, while riding in a street car, he turned his head suddenly to look out of the car window and was seized with a severe pain in the neck. Since that time the motions of the head upon the neck have gradually become less free, and have been attended by a more or less constant but steadily increasing amount of pain. Two weeks later he noticed a swelling on the back of

the neck, which has increased in size, and he complains at times of chills and fever.

Physical examination showed a well-developed and nourished man, somewhat pale, with flushed cheeks and a distinctly septic facies. The head was held rigidly to one side, with the chin depressed and pointing somewhat toward the right shoulder. Over the occipito-axoid region, somewhat to the right of the median line, was a thick, brawny, indurated swelling, non-fluctuant and distinctly tender to pressure.

The patient could not turn his head in either direction, and could open his mouth only with difficulty. The motions of the cervical spine were restricted in all directions, but the restriction seemed more the result of mechanical interference, due to the swelling itself, than upon spasm of the cervical muscles.

Examination of the throat showed no retropharyngeal or peritonsillar abscess. His temperature was 100.4° and pulse 100.

An x-ray showed the shadow of an abscess, and a thickening and fusion of the bodies of the second and third cervical vertebrae. Three days later he was admitted to the wards with a temperature of 103° and a pulse of 100.

On Jan. 24 an incision was made just to the right of the median line, opposite the second and third cervical vertebrae, and several drachms of thick creamy pus were evacuated, which on bacteriological examination showed the presence of the staphylococcus pyogenes aureus in pure culture.

A sharp fall in the temperature was at once noted, and in a few days the motion of the neck became freer, and pain was much relieved.

The temperature remained between 99° and 100° for about ten days, when on removal of the drainage tube the abscess reformed and the temperature again rose to 103°. At this time a second operation was done by the writer. The original opening was enlarged and an incision three inches long was made to the left of the median line with dissection down to the spinal column; considerable pus was evacuated and drainage tubes were placed in each opening. The temperature again fell to normal, and further convalescence was uneventful. Both wounds were allowed to granulate from the bottom, and at the present writing, one year after the operation, they are completely healed, all motions of the cervical spine are quite within normal limits, and there are no subjective symptoms.

Acute osteomyelitis of the spine is clinically a rare condition. In 1875 Delafield¹ showed the Pathological Society of New York a specimen of a vertebra found at autopsy in the case of a man sixty-three years of age, who was admitted to the Roosevelt Hospital complaining of steady pain in the lumbar region; loss of weight, followed within a few weeks by paralysis, pyemia and death.

In 1896 Makins and Abbott² of London reported six cases of their own with postmortem records, one each by Lucas, Ballance, Hahn and Müller, together with eleven from the literature in which they found the following data as regards age and location: Under 2 years, 1 case; 2 to 5 years, 2 cases; 5 to 10 years, 2 cases; 10 to 15 years, 8

¹ New York Med. Journ., 1875. xxi, 53.

² Annals of Surgery, 1896. xxiii, 510-539.

cases; 15 to 20 years, 3 cases; 20 and over, 3 cases; not stated, 2 cases.

The cervical region was affected in 3 cases; the dorsal in 5 cases; the lumbar in 10 cases; sacral in 1 case; not recorded, 2 cases.

As regards frequency of occurrence Hahn,³ employing the statistics of Frohner⁴ and Haaga,⁵ found that in 661 cases of infectious osteomyelitis the long bones were affected in 610 instances, the short and flat bones in 51, or 7.7%. Among the short and flat bones only one vertebra was found affected.

In 41 fatal cases of acute infectious osteomyelitis occurring in seventeen years at St. Thomas' Hospital⁶ only one instance of an affected vertebra is recorded.

Otto Hahn,⁷ in a recent study of a series of 41 recorded cases, gives the following data and general conclusions:—

(1) Sex: Twenty-three males, 12 females and 5 unknown. (2) Age: The great majority occur in the first two decades of life, being distinctly a disease of youth. (3) Location: Cervical, 7 times; dorsal, 12 times; lumbar, 17 times; sacral, 5 times. (4) Etiology: Evidence of undoubted trauma occurred 6 times. In 15 cases there was a history of trauma, in 10 instances the patient was perfectly well up to the onset, 3 cases were secondary to the disease elsewhere, and in one case a purulent paronychia was present; in the remaining cases no definite etiological factor was determined.

Results of treatment.—He reports a mortality of 60%, and gives the following causes of death: Pachymeningitis, 2 cases; extensive pneumonia, 2 cases; retropharyngeal abscess, 1 case; empyema, 2 cases; gravitation abscess, 6 cases; amyloid disease, 1 case; invasion of the cord, 8 cases.

His general conclusions are as follows: That while the etiology and course of acute osteomyelitis of the spine is often the same as that in other bones, yet severe complications are not uncommon, because of the ease of the extension of the suppurative process into the central nervous organs; that the diagnosis is in most cases easily made but the complications dependent upon the early invasion of the spinal cord, brain and other organs, as well as the pyemia of early onset, render it at times very difficult. The prognosis is grave, but depends upon the character of the infection, the situation of the disease, the general condition of the patient and upon early diagnosis.

Treatment to be effective should be begun as soon as the diagnosis is made, and should be radical. It is, however, limited where the process has already involved the central organs or where other serious complications, as, for example, pyemia, are present.

Medical Progress.

RECENT PROGRESS IN SURGERY.

BY HERBERT L. BURRELL, M.D., AND HAYWARD W. CUSHING, M.D.,
BOSTON.

TETANUS GERMS IN GELATINE.

The work of Levy and Bruns¹ in investigating commercial gelatine with regard to the presence of tetanus micro-organisms shows positive results. The tetanus spores were demonstrated in eight out of fifteen samples. An attempt was also made to determine how they could be destroyed. Text-books were found to state that exposure of tetanus spores to live steam at 100° C. for eight minutes would destroy them. The experimental work of Levy and Bruns is reported to show that in one and the same culture the power of resistance was quite different in different individuals. Some perished in four to six minutes; the most resistant in after thirty minutes. It was not definitely known if the gelatine might not lose its power to control hemorrhage if heated above 100° C. So the sterilizing temperature was not carried above that point. P. Krause² also, after an extensive review of the literature of the subject and a large number of personal investigations, reports the following conclusions: (1) That the reported cases of tetanus infection have resulted from an insufficient, faulty sterilization of the gelatine. (2) Certain sterilization results from fractional sterilization; exposure to live steam at 100° C. for one half-hour, on five successive days.

THE "RED-ROOM" TREATMENT OF ERYSIPELAS.

H. Krukenberg³ (Liegnitz) has contributed another method of treatment to the long list already on record, and one which seems to have impressed him by its apparent efficiency. Concisely, it consists of exposing the patient to red light. Konkenberg has based his conclusions on his experience with thirteen patients. The average duration of the fever was reduced to only two days. There were no severe general symptoms. After twelve hours the line of demarcation was no longer to be determined, and often finally a fine desquamation appeared. Recurrence occurred in four cases, when the red light was discontinued. He suspects that the effect of applications used in the treatment of this disease may be due to the shutting out of light; for example, tincture of iodine, ichthyl and similar non-transparent substances. Also he claims

hat skin exposed to the sun is a frequent site for the disease; also that the colored races show less susceptibility to it.

THE EFFECT OF THE "FINSSEN" TREATMENT OF LUPUS, RODENT ULCER AND NÆVUS VASCULOSUS PLANUS.

The work which has led to the recognition of the histological-pathological process in the healing of affections of the skin, under the influence of the concentrated electric arc-light, has arisen, not from the Institute of Finsen, but from Russian investigators (Glebowsky, Pitnow, Gerschury), after the reaction of the healthy skin to the electric arc-light was first studied by Möller. From the observations of the former observers the following is obtained: The first effect of the action of the light is on the blood vessels, in whose walls the first changes, such as swelling and growth of the endothelium, is recognized. The process of repair has nothing to do with cauterization or burning of the diseased tissues. The action is rather a pure elective one, in so far that only the diseased cells and those having slight power of resistance undergo degeneration, while the other elements within and without the diseased area are aroused into activity. It is, then, a weakening of the pathological and a strengthening of the healthy elements in the area affected by disease and its vicinity, as the biochemical product of the "Finsen" process, in contra-distinction to the purely passive method, when both the healthy and diseased parts are destroyed by the thermo-cautery or caustics, and thereby the possibility for the still-surviving elements to defend themselves by their own productive vitality from the internal enemy.

ANCHYLOSIS OF THE TEMPORO-MAXILLARY ARTICULATION FOLLOWING TRAUMATISM.

M. Gindus⁴ has published an historical review of the treatment of bony ankylosis of lower jaw and discussed the anatomy of its articulation with its bony surroundings, also the etiology of the lesion and its pathology. The subject is an important one. The most frequent causes of irreducible dislocations are stated to be fractures of the neck of the condyloid process, injury or pressure ("Impressionen") of the glenoid fossa, arthritis from different causes. The especial frequency in young people, the anatomical classification and the osteo-osteoplastic peculiarity of the periosteum, explain the noteworthy ossification of the joint. The inflammatory reaction of the periosteum is considered anatomically and pathologically. One has to determine diagnostically the presence of cicatricial bands or contraction of the muscles of mastication. The presence of these justifies the assumption of the presence of a bony ankylosis, which is in most cases unilateral. The prognosis from mechanical reasons is a bad one, on account of which the treatment is definitely indicated. It consists solely of resection of the condyloid process which in all cases gives a good result, namely, a pseudarthrosis in place of the old joint. In operating, especial care is taken not to injure the facial nerve. In conclusion is described a successful operation in a patient of Roux's aged sixteen.

⁴Revue Med. de la Suisse romande, 1902, No. 1.

OPERATIVE TREATMENT OF TUMORS OF SUPERIOR MAXILLA.

Stein⁵ states, in summing up the results of his experience, that operation is to be advised in every case in which the tumor is progressing. As Estlander noted in 1879, the patient who has a sarcoma of the superior maxilla has only about one year and a half from the onset of his disease to live, and, as a rule, these cases do not present themselves for treatment until a year of this time has passed. Without operation there is no hope, while with it the average mortality is 17% (in the author's hands it has only been 12½%); there is an equal chance of being permanently cured, another just as great that life will be prolonged for a year or so, and there will usually be complete relief from pain.

CARCINOMA OF THE LIPS.

Janowsky,⁶ as a result of an extensive review of the literature, states in conclusion: (1) The operation for carcinoma of the lips should not be considered as dangerous, and in the greater majority of cases union by first intention takes place in from nine to fifteen days. (2) All the lymphatic glands of the submental and submaxillary region must be removed, or recurrence will occur. (3) When necessary the inferior maxilla may be resected without danger. (4) The lymphatic glands are affected soon after the onset of the disease, — in two or three months, — but this should not prevent a radical operation from being successful. In many cases the glands are involved when not palpable, and recurrence will follow if they are not removed. (5) In 49% of the operated cases the end results were good. (6) In the cases which had recurrence the disease reappeared in the greater majority of the cases within six months and nearly all the rest within the first year; in only a very few cases was the recurrence after a lapse of one or two years. (7) When recurrence took place it was generally found at the point where the disease first appeared or else in the submental region. (8) The operative results were influenced by the duration of the disease and the degree of malignancy in each particular case. Cases which were not severe were operated on successfully as late as several years after the onset of the disease. (9) Old age is not a contraindication to operation; the best operative results were obtained in patients between sixty and seventy years of age. (10) In cases of recurrence a second operation is only palliative, and possibly may prolong life for several years. (11) Carcinoma of the upper lip is nineteen times less frequent than that of the lower lip, and carcinoma of the lip is ten times more frequent in males than females. In women carcinoma of the upper lip is five times more frequent than it is in men. (12) After a careful study of one hundred and seventy-eight cases, it is impossible to state that carcinoma of the lips is more frequent in any occupation or station in life than in any other. (13) The disease is most common in persons between the ages of sixty and seventy years. (14) Twenty-five per

⁵Archiv f. klin. Chir., 1902, Band lxx, Heft 2; Journ. Amer. Med. Sci., July, 1902, p. 159.

⁶Archiv f. klin. Chir., 1902, Band lxx, Heft 2; Amer. Journ. of the Med. Sci., June 2, 1902.

cent of all cases are rapid in growth and markedly malignant, 15% are less severe, while the remaining 60% are a compromise between these two.

THE CAUSE OF SECONDARY HEMORRHAGE.

Secondary hemorrhage, post-operative, frequent as it was formerly, occurs today essentially only with purulent inflammation of cellular tissue, according to the conclusions of A. Frommer,⁷ who reports his investigations in eight cases. The histological conditions show that the suppuration process invades the vessel walls from the surrounding tissues, producing in the same purulent inflammation with resulting degeneration and necrosis. The tendency to hemorrhage by erosion of the vessel wall depends on the intensity of the infection and the virulence of the bacteria. As regards the control of hemorrhage in such cases, packing the wound and compression bandages always are unsuccessful, according to Frommer, for the bleeding, although temporarily checked, in most cases recurs in a manner to threaten the life of the patient. He regards the proper treatment to be the ligation of the artery in healthy tissue. The article is practically a confirmation of the ideas held by surgeons before the bacteriological era, except that the histological and bacteriological data was not then at hand.

THE ANASTOMOSIS OF THE PORTAL VEIN WITH THE VENA CAVA. — A NEW OPERATIVE PROCEDURE.⁸

Tansini states that the advantage of the diversion of the blood from the portal vein is unquestioned for the relief of certain conditions, and the objection to the method of Talina is that this is accomplished indirectly and not always completely. The author's method has been tried with success on dogs, and consists in an end-to-side anastomosis of the portal vein with the vena cava. Clamps covered with rubber are placed over the veins in order to control hemorrhage, and the portal vein is cut. Then a small spindle-shaped piece of the vena cava is cut out between the clamps, the end of the portal vein is inserted in the opening and the edges closed with silk stitches and the clamps removed. Each one of the dogs experimented upon became fat, and was perfectly healthy when killed two months later. Examination at this time showed the union between the veins to be perfect.

(To be continued.)

Recent Literature.

Surgical Diseases of the Kidney and Ureter, Including Injuries, Malformations and Misplacements. By HENRY MORRIS, M.A., M.B. (Lond.), F.R.C.S., Fellow and Chairman of the Court of Examiners of the Royal College of Surgeons; Senior Surgeon to the Middlesex Hospital; Honorable Member of the Medical Society of the State of New York. Author of the Hunterian Lectures (1898) on "The Origin and Progress of Renal Surgery," of "Injuries and Diseases of the Genital and Urinary Organs," and of "The Anatomy

of the Joints," etc. Editor of a "Treatise on Human Anatomy by Various Authors." With two colored plates, and upwards of two hundred engravings. In two volumes. London, Paris, New York and Melbourne: Cassell & Co., Limited. 1901. W. T. Keener & Co., 90 Wabash Ave., American Publishers. (American edition announced for 1903.)

This work bears the stamp of authority derived from the personal experience of an eminent surgeon, and fulfils the expectation of excellence that is warranted by Mr. Morris' previous contributions to medical literature. It is conspicuous for the well-balanced judgment and convincing quality of the conclusions with which the author treats the various problems included in his subjects. The large number of personal observations and the concise manner in which they are presented lends a strong flavor of originality to the work and adds much to its value; at the same time there are included in it the more important results of other men's work. It is not too much to say that this is the best practical treatise upon the subject extant in the English language.

The position taken with reference to several questions is advanced, and so well sustained as to carry conviction. As an example of this may be cited the author's advocacy of nephrotomy as a life-saving measure in cases of calculous anuria, a matter to which the attention of the profession needs to be directed.

In a publication of such uniform excellence as this is, it is unnecessary to comment in detail upon its good qualities, and we have only to say that we unreservedly commend it and its teachings to the profession.

American Edition of Nothnagel's Practice. Diseases of the Stomach. By DR. F. RIEGEL, Professor of Clinical Medicine at Giessen. Edited, with additions, by CHARLES G. STOCKTON, M.D., Professor of Medicine in the University of Buffalo. Authorized Translation from the German under the Editorial Supervision of ALFRED STENGEL, M.D., Professor of Clinical Medicine, University of Pennsylvania. Philadelphia, New York, London: W. B. Saunders & Company. 1903.

This is an octavo volume of 835 pages illustrated by six full-page plates in addition to minor drawings. It is the fifth volume of the American edition of Nothnagel's Practice. The whole volume is devoted to diseases of the stomach. The subject is treated in an exhaustive manner, and the bracketed revisional notes of the American editor, Dr. Stockton of Buffalo, thoroughly represent the latest contributions to the subjects under consideration.

Part I deals with the general diagnosis and treatment of diseases of the stomach; Part II with special diagnosis and treatment of diseases of the stomach. The chapters on the nervous affections of the stomach, and the different forms of gastric neuroses, seem to us of especial interest. The pages on gas fermentation and the abnormal products of fermentation and putrefaction, on the disturbances of mobility and of secretion, are good examples of the excellence of this volume, which can be strongly recommended to those who are occupied with the diseases of the organ to which it is devoted

MEDICINE IN RELATION TO LAW.

WE have from time to time alluded to the series of lectures which have this year been given on various topics on the physician's relation to the community, under the auspices of the students of the Harvard Medical School. A recent address in this course was given by Hon. Moorfield Storey, on the relation of the physician to the law. In introducing Mr. Storey the chairman said that it is a matter of common report that one of the weakest, if not the weakest, point in the average physician is his inability to appear to advantage in the court room. However true this may be, it is certainly eminently desirable that young medical men, as well as those of riper experience, should present a dignified appearance when offering their testimony in court. That this is by no means always the fact is a matter of commonest observation, arising, no doubt, in great measure from ignorance on the part of the medical witness of his rights and duties when called upon to testify in matters regarding expert knowledge.

Mr. Storey's somewhat informal remarks, published in the *Quarterly of the Harvard Medical Alumni Association*, should have been most helpful, not only to the undergraduates, but also to any others who were fortunate enough to hear him. He insisted at the outset upon the very close relationship between law and medicine in the administration of justice, and the absolute dependence in many cases which the law must place upon medical expert testimony in bringing a criminal to justice or determining the rights of individuals. He drew a distinction, which is not always recognized, between what is expected of medicine and what is expected of law in determining responsibility. "The medical man will tell you exactly how incapable a person is. The law will say whether that

degree unfits him for will or contract." The doctor in his medico-legal relations deals simply with facts as facts. He is not concerned with consequences. It is his business to tell precisely what he finds, what he sees, what his opinion is as to causes or consequences. Beyond this he has absolutely no responsibility for the consequences which the law attaches. This distinction is an important one, and should certainly be clearly recognized in pursuing those investigations in which both law and medicine must co-operate to reach satisfactory conclusions.

The discussion which follows regarding the jury system is of interest, and is naturally what one would expect from the lips of a member of the legal profession. It is maintained that justice on the whole is best subserved by the completest possible expression of the claims of two sides in controversy, ruled over by the decisions of a judge, and finally decided upon by a supposedly unprejudiced jury, aided as the case demands by expert testimony on the two sides. It is understood that the lawyer is necessarily and properly a partisan, but that the doctor should never be; that the doctor goes into court not to help either side, that he is there to express the facts merely, not to make himself, as is sometimes said, "the counsel in disguise." The failure to recognize this limitation accounts, in Mr. Storey's opinion, for the disrepute into which many experts have fallen, and to their partisanship, which is often too apparent in legal proceedings. From the point of view of the doctor, who is often not used to the ways of the law, it must be remembered that he is usually placed at a very decided disadvantage, and that much of his partisanship is rather in appearance than in fact. It cannot be doubted that a clever lawyer can always, in the eyes of the jury, force a witness into an appearance of partisanship, for which the doctor is at least only partially to blame.

What Mr. Storey says of the rights of the doctor should be widely understood. He is not obliged, as popularly thought, to answer questions by Yes or No, if the answer would thereby lead to a false impression; nor is it possible to answer certain questions in such a categorical fashion, as, for example, the question, "Have you given up beating your wife?" The use of technical terms is absolutely condemned. The cultivation of a pleasant manner is urged. The avoidance of temper and of "smartness" is insisted upon. The failure to recognize any of these simple rules places the witness at the mercy of the counsel. In addition to what we have already suggested, Mr. Storey expresses many vigorous opinions on unscrupulous medical witnesses and on unscrupulous legal methods.

It is certainly true that few physicians go through life without being called once or many times to testify in matters which require expert judgment. It is also true that relatively few medical men make really good witnesses. They fail either to recognize their responsibilities or their rights. The one error leads to just criticism, and the other to a misrepresentation of the facts, which places the physician in an entirely false attitude. We should certainly agree with Mr. Storey when he implies that simple honesty in the court room, as elsewhere, will never lead its possessor astray.

CANCER IN IRELAND.¹

In an address before the Congress of Tuberculosis in London, in 1901, King Edward made the following allusion to cancer: "There is still one other terrible disease, which has, until now, baffled the scientific and medical men of the world, and that is cancer. God grant that before long you may be able to find a cure for it, or check its course!"

With a loyal spirit of investigation the registrar-general of Ireland has taken up the subject and published such information as could be gathered from the statistical sources in his possession, supplemented by the results of a special inquiry addressed to the local registrars of Ireland.

The report just published has special value from the fact, as the registrar-general states, that "the notes have been in almost all cases furnished by medical practitioners." It also has further value in the comparative tables, publishing similar figures for other countries, including the New England States and Michigan. Not very much added information, however, appears to have been secured upon the general subject of cancer, beyond what was published in Dr. Whitney's recent report upon "Cancer in Massachusetts."

Cancer appears to have increased in Ireland as shown in the following table:

| | Years and Deaths | | | | |
|------------------------------|------------------|-------|-------|-------|-------|
| | 1897. | 1898. | 1899. | 1900. | 1901. |
| Number deaths from cancer, | 2,635 | 2,657 | 2,654 | 2,717 | 2,893 |
| Rate per 10,000 living . . . | 5.8 | 5.9 | 5.9 | 6.1 | 6.5 |

These figures for Ireland are less than those of England and Scotland for the same period.

In 1864 the death-rate from cancer in England was 3.9 per 10,000, in Scotland 4.5, and in Ireland

¹ Special Report on Cancer in Ireland, with statistical tables and observations as to the prevalence of the disease; also notes on the history of cancer cases (being a supplement to the Thirty-eighth Annual Report of the Registrar-General). Dublin, 1903.

only 2.7; while in 1900 they had risen in England to 8.3, in Scotland to 8.0, and in Ireland to 6.1. In each of the New England States and in most of the large cities of the world the death-rates from this cause were higher than those of Ireland.

The map and table published with the Report show that cancer was more prevalent upon the east coast of Ireland than upon the western; County Armagh, in the province of Ulster, having the highest death-rate (10.5 per 10,000), and County Kerry, in the extreme southwest, having the lowest (2.6).

When the question of age is considered, the statistics of cancer in Ireland, as compared with those of other countries, are quite different from the results which might have been expected, since the relative number of old people, among whom cancer causes the greatest number of deaths, is larger in Ireland than it is in other countries, as a consequence of the rapid depletion of its young and vigorous population by emigration.

The population of Ireland over fifty years of age constitutes about 19% of the whole, while in England the population of the same ages is but 14.4% of the whole, so that a lower death-rate from cancer might have been looked for in England than that of Ireland, but the contrary is the fact, as shown by this report.

There is also a difference in the relative death-rate of the sexes, since the deaths from cancer in England in 1900 were shown to be in the ratio of 1,000 males to 1,551 females, while in Ireland in the same year they were in the ratio of 1,000 males to 1,252 females.

An interesting part of the report consists in the observations sent in by the registrars, most of which are contributed by medical men. From these observations the registrar-general condenses the following summary:—

(1) That in many cases cancer recurs in the same family—grandparents, parents and other relatives of the person affected having suffered from that disease.

(2) That frequently where a member of a family is afflicted with cancer, other members of the family suffer from tuberculosis.

(3) That in a number of instances where members of a family are afflicted with cancer, other members of the family suffer from lunacy, idiocy, or epilepsy.

(4) That in several cases cancer has appeared where there is a history of syphilis.

(5) That in some cases the disease has occurred in persons who have been in direct contact with cancer patients.

(6) That the disease has manifested itself in individuals who have used the tobacco-pipes of persons suffering from cancer of the lip.

(7) That in some instances more than one case of cancer has occurred amongst different families living in the same house, or amongst successive occupants of the same house.

(8) That in a few cases the disease has appeared in different houses in the same locality about the same time.

(9) That cancer not infrequently appears after wounds and injuries.

(10) That in some cases cancer has supervened where there has been irritation of the lip consequent on smoking clay pipes.

(11) That cancer frequently shows itself where unfavorable conditions as to residence, food, etc., exist.

THE PUBLIC MILK SUPPLY.

HERE is a matter in which Massachusetts still lags behind when she should be in the van. She may well point with justifiable pride to her truly pioneer work in the education of the people in the advantages of a pure water supply and the manner of obtaining it, in the evils of faulty sewage disposal and the details of proper methods, for in these matters she has set an example quickly followed by other observant and progressive states; but in the question of a milk supply she has not only failed to establish the criterion, but she even pauses long in accepting the illuminating leadership of others. The reason for this lamentable lack of progress might at first sight be ascribed to those intangible scapegoats "the authorities," supposedly in this instance the legislators, the health boards, the sanitarians, the "faculty;" but a closer consideration seems to implicate instead chiefly that inveterate enemy of progress, the deficient education of a majority of those most interested in reform. Who could have a more essential interest in the purity of milk than the consumer, but who, as a matter of fact, is more in the dark than he in regard to the present extremely unhygienic and dangerous methods of milk production and distribution, as well as to the possibilities of their improvement?

The conditions under which the general supply of our large metropolitan districts is handled must rest as a flagrant disgrace until some movement for reform is made. These conditions have long since been noted and described by expert investigators; attention has been called to the unsanitary condition of stables, and of the storing shed or aging cellar, where the milk waits for part of the twenty-four to seventy-two hours' ripening period, which the prevailing practice of distribution makes obligatory. The luxuriant flora of this stale and partly fermented milk has been demonstrated time and again. But such information has thus far failed to strike home, has not reached the general public, who still imagine that the important contributions to our literature on milk are comprised in the semi-annual discussions current in the daily press between producer and distributor, as to whether the

consumer shall pay so much more or less per quart than he did last season.

Meantime the legislators, apart from prohibiting the adulteration of milk, and the feeding of cows with improper food, content themselves with a statute decreeing that while, during April, May, June and July, market milk will pass muster if it contains 12% solids, it must during the rest of the year conform to a 13% standard—a practical application of the almanac about as sensible as invoking the equinox as a date for changing one's flannels. Obviously, health boards and official inspectors, to accomplish genuine reform, need more comprehensive legislation than can at present be considered possible of enactment.

The sporadic establishment of milk laboratories, so called, and of dairies, exploiting expert justification from their display of attractive legend on wagon and bill-head, has accomplished much good in the way of calling attention to the possibility of producing and marketing a milk which satisfies such a standard as should be required by law; but so far the number of these establishments has been too small to stimulate a general interest in improvement, and purity has been stamped as a luxury rather than as a *sine qua non*.

Twelve years of continued and increasing success of the Strauss depots in New York have failed to call from the lines of our own philanthropists one to emulate this great charity which helps without pauperizing, which instructs in the principles of purity without mystifying with the mechanics of modification, and which has served in the opinion of competent authority to cut down by one half infant mortality in the Borough of Manhattan during the summer months. In thus supplying at moderate cost a pure and under ordinary precautions an incorruptible milk to that portion of the population which most needs it, there surely exists a most efficient way of dispensing a portion of the contributions which never fail in worthy causes.

But given or failing a Strauss, there still remains much to be done for the advantage of those who can afford to buy pure milk at the slight increase in expense which purity entails, and fail to do so simply because they lack information in regard to the dangers of the impure article and the feasibility of ensuring for themselves a standard product. It is to this end that milk commissions have been formed in Washington, Philadelphia, New York and Newark, and in the few years of their existence they have triumphantly justified themselves. The inspiration for their formation has generally originated with one or more physicians or with a medical society, and the members of the commis-

sions are chiefly, if not solely, members of the profession. Their self-imposed function is to issue to such milk producers as apply for them certificates of approval, if, on careful examination by chemist, veterinarian and bacteriologist, all in the employ of the commission, the dairy, its methods, its surroundings and its products are found above suspicion.

Such visits of inspection are made within certain intervals but on unannounced dates, and the certificate is subject to renewal or withdrawal according as the very complete regulations of the commission are followed or not. The advantage accruing to certified dairies in increased patronage has made application for approval prompt and continuous, and the cost of inspection paid by the producer has been readily covered by the moderate advance in price at which the certified product is sold.

Since no one can gainsay the need of such a commission in our own community, the question may well be asked, Why delay longer in forming it?

STATE PRODUCTION OF ANTITOXIN AND VACCINE.

DURING the early part of the present legislative session a bill was introduced on behalf of the Board of Health of the city of Boston, and largely endorsed by the medical profession, all of the large medical societies and local boards of health, as well as by many prominent citizens, providing that the State Board of Health "may for the use of the people of the Commonwealth produce and distribute vaccine lymph."

After many weeks of deliberation, following a free discussion of the subject at hearings before the legislative Committee on Public Health, this committee has submitted, through its Senate chairman, two bills (Senate Nos. 367 and 368), in which the subject is divided in such a manner as would, if enacted, put the State to unnecessary expense, cause inconvenience and delay in distribution, and undoubtedly prove an ultimate failure, so far as an important part of the work is concerned.

Senate Bill No. 367 provides that the State Board of Health "may produce and distribute antitoxin to public charitable institutions and to the worthy poor." This provision limits the distribution of antitoxin to a certain indefinite class of the population, and is defective in that it provides no means of determining what persons shall be included in the meaning of the term "worthy poor." Moreover, the taxpayers of the Commonwealth who pay

largely for the *production* of the antitoxin are entirely shut out from the benefits of its *distribution*. So great has been the success of the method of distribution, as well as the quality of the product furnished by the State Board of Health, that such a limitation would undoubtedly prove a hardship, and result in loss of life in some parts of the State, where delay would necessarily take place in procuring and keeping on hand antitoxin of private manufacturers.

The absurdity of Senate Bill No. 368 is even more patent than that of No. 367. By the terms of this bill it is seriously proposed that the State Board of Health shall cause "vaccine lymph to be produced under its direction at the Massachusetts Agricultural College, for free distribution throughout the Commonwealth."

The State Board of Health has thus far produced its antitoxin at the Bussey Institution at Forest Hills, and within easy reach of the central office of distribution. The work is conducted under the supervision of a competent director, Dr. Theobald Smith, and has secured the absolute confidence of the medical profession using it, as well as that of the people at large, for whose benefit it has been produced. No one has objected to the method of production and distribution, nor to the place where it is produced, except those persons who are commercially interested to defeat any movement which shall extend the same methods to the production of vaccine lymph.

The senseless scheme of dividing this work in such manner that two allied processes of production must be conducted in two establishments one hundred miles apart, which can be far more economically and conveniently carried on in one place, quite near the point of distribution, must be plain to every one who has at heart the interests of public health.

To any one who has watched the progress of state legislation in Massachusetts for twenty years or more, any effort to combine the work of boards or commissions not having closely allied functions appears extremely grotesque. Under the fear of certain characteristic threats of General Butler a board of Health, Lunacy and Charity was organized in 1879, but this unfortunate combination proved a conspicuous failure, and the three separate boards of Health, of Insanity and of Charity are now doing far better work than it was ever possible to accomplish under this short-lived organization.

This bungling attempt to establish a station for the manufacture of vaccine lymph in the Connecticut valley at a distance from the principal part of the population destined to use it, as well as from

the central office of distribution, deserves the commendation of disinterested citizens.

The original bill, House No. 329, is amply sufficient to legalize the contemplated work, and only needs a sufficient appropriation to ensure a successful result. It is an economic, humane and life-saving measure, and merits professional support throughout the State.

MEDICAL NOTES.

A LEGAL RULING AGAINST CHRISTIAN SCIENCE. — It is stated that the Supreme Court of Pennsylvania has affirmed the ruling of the late Judge Arnold, refusing to grant a charter to a Christian Science association. The charter was previously refused on the ground that "it would be injurious to the community to incorporate a group of citizens who could preach the doctrine that there is no such thing as a contagious disease, or any disease, and practice the art of curing of what are called contagious diseases by inaudible prayer whether in the presence of the sick or at a distance." The Supreme Court has found no reason for reversing the previous decision, holding that when persons make business of practising medicine without registration they violate the law intended to prevent medical practice by non-qualified persons.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, May 6, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 36, scarlatina 33, typhoid fever 12, measles 31, smallpox 0.

SMALLPOX. — It is reported that three cases of smallpox have recently occurred in Leominster, Mass. The patients have been removed to the isolation hospital.

THE INSANE IN ALMSHOUSES. — Before the Committee for Public Charitable Institutions, of the Massachusetts Legislature, a bill amending the act of 1900 relating to State care of the insane was introduced, permitting certain of the harmless and quiet insane to be maintained in almshouses throughout the State. There are now about nine hundred of this type in almshouses, and it was urged that by forthwith transferring them to the State institutions for the insane these institutions would be unduly crowded, and proper provision could not at once be made for them. There was no opposition to this bill.

NEW YORK.

MORTALITY STATISTICS. — The weekly reports of the Health Department show that the mortality in the city during the month of April represented an annual death-rate of 18.47 against 19.67 in March and 19.83 in April of last year. The corrected death-rate, excluding non-residents and infants under one week old, was 17.50. Among the diseases which showed a decline in mortality are the following: The weekly average of deaths from typhoid fever decreased from 10.25 in March to 7.25 in April; of deaths from measles, from 10.25 to 7.75; from influenza, from 33.25 to 10.5; from pneumonia, from 178.5 to 143; from broncho-pneumonia, from 83.25 to 72.5; from acute bronchitis, from 37.5 to 36.5; from pulmonary tuberculosis, from 171 to 162.5; from cancer, from 55 to 51; from nephritis, from 130.5 to 111.25, and from whooping-cough, from 8.25 to 5.25. Among the few diseases which showed an increased fatality are scarlet fever, in which the weekly average of deaths increased from 16.5 to 23.5, and diphtheria and croup, in which the weekly average increased from 46 to 48.75.

SITE FOR TUBERCULOSIS HOSPITAL. — At a meeting of the Medical Society of the County of New York, held April 27, a resolution was adopted requesting the governor to veto the bill passed by the legislature concerning a site for the proposed tuberculosis hospital for New York City. The bill necessitates the consent of the boards of supervisors and aldermen to the selection of the required site, and this, in the opinion of the president of the health department, would practically kill all chances of getting a location for the hospital.

REGISTRY OF TRAINED NURSES. — The governor has signed the Armstrong Bill passed by the legislature, which provides for a system of registry for trained nurses in the State, under the auspices of a board of examiners to be appointed by the regents of the University of the State of New York. The examiners are to be chosen from a list of ten members of the New York State Nurses' Association, nominated by the association. Nurses passed by the board, and certain nurses qualified by long service prior to the passage of this law, are entitled to the designation of Registered Nurse, and to attach the initials "R. N." to their names.

SITE FOR THE ROCKEFELLER INSTITUTE. — Final contracts have been signed for the purchase from the Schermerhorn estate of the site, on the East River, for the proposed laboratory of the Rockefeller Institute. The work of construction will not be begun, however, until after the first of August. The purchase price is stated to be about \$700,000.

GIFTS. — By the will of the late Adolph Openhym, in addition to other charitable bequests, \$5,000 each is left to the Mount Sinai Hospital and the Montefiore Hospital and Home for Chronic Invalids. The latter institution has also just been presented with a gift, by S. R. Guggenheim, of five hundred shares of the preferred stock of the American Smelting and Refining Company, having a par value of \$100 a share. The object of the donation is to establish a permanent fund, the income from which may be used by the trustees for any purpose they see fit.

By the will of the late Samuel D. Babcock, \$20,000 is bequeathed to St. Luke's Hospital.

TREPANI CONVICTED. — Trepani, the Italian undertaker, who was one of the principal agents in the extraordinary scheme to defraud life insurance companies, described in the *JOURNAL* of Feb. 26, was, on May 1, found guilty of grand larceny in the first degree, the maximum penalty for which is imprisonment for ten years. Cirone, the barber, the other leader in the conspiracy, died some time ago in another state, where he had gone to evade arrest.

DAMAGES FOR STREET RAILWAY INJURY. — Dr. Justin Herold has been awarded \$12,000 damages by the verdict of a supreme court jury, in a suit brought by him against the Metropolitan Railway Company for personal injuries received in May, 1900. His foot was crushed, and during the trial radiographs showing the condition of the parts were put in evidence. Dr. Herold, who was formerly a coroner's physician, has paid special attention to the study of medical jurisprudence, and has been called as an expert in a large number of trials of various kinds.

THE CORONER SPARED. — Among the bills which failed to pass at the recent session of the Legislature was the one abolishing the office of coroner in New York.

A CENTENARIAN. — Mrs. Margaret Cope, the last of three sisters, the youngest of whom was ninety at the time of her death, died in Mount Vernon, Westchester County, N. Y., on April 24, aged one hundred and one years.

MUZZLING OF DOGS. — At a meeting of the New York County Branch of the New York State Medical Association, held April 18, resolutions were adopted setting forth that when muzzling of dogs was enforced in Berlin and other European cities, hydrophobia entirely disappeared from them, and urging the passage of an ordinance establishing a similar regulation for the city of New York.

NOTES FROM THE PHILIPPINES.

A GENERAL HOSPITAL FOR MANILA. — The insular government has decided to construct and

maintain a general hospital in Manila, open to all nationalities, provided a site for the institution is furnished gratuitously. A large part of the funds necessary for the construction of the hospital have been secured by popular subscription from the American, European, Filipino and Chinese residents, through the energies of the Hospital Committee, of which Bishop Brent is the chairman. The expense of operating the hospital will be borne by the insular government. The plan of the proposed hospital is understood to be based on that of the Boston City Hospital, modified to suit local and climatic conditions. The committee has several sites for the institution under consideration, but one in the elevated city suburb of Santa Mesa is regarded with most favor. This site is generally excellent, and is on the line of the new trolley system, upon which the work of construction is soon to be begun.

PLAGUE. — Bubonic plague is still on the increase in Manila, despite the efforts of the health authorities. During the month of February there were eighteen cases, of which thirteen proved fatal. During the month of March forty-three cases developed. The disease attacked Filipinos for the most part, though a number of Chinese were among those stricken. So far, scarcely any cases have occurred among whites during the two years in which the disease has maintained a foothold in Manila. Where it has attacked Americans, these have always been of the lowest class who have been living with native women in the slums of the city. While bubonic plague does not yet exist in an epidemic form in the city, no district appears to be free from the infection, and a case lately occurred in the Ermita district, the best residential section of Manila. The disease is purely of the bubonic type, and manifests little tendency to spread. So far, no cases have been reported as occurring in the islands outside of Manila. The mortality of those attacked, both in this city and in Hong Kong, is high, probably 90% for Chinese and Filipinos. In Hong Kong the mortality among the whites actually attacked has been 65%; though, as in Manila, few Caucasians have suffered.

CHOLERA. — During the past few days there has been a decided tendency toward an increase of cholera in the provinces, and its reappearance in places in which it had for months been regarded as extinct. The southern portion of Luzon and the southern islands still have many infected points, from which the disease will certainly spread with the beginning of the rains. The Board of Health expects widely spread outbreaks during the rainy season, but not of the severity of those of the past

year. In the epidemic of 1883-84 the outbreak was much like that of the present, and the epidemic ceased abruptly toward the end of the second rainy season, after a severe typhoon, lasting three or four days.

PROHIBITION OF SALE OF OYSTERS.—For some time the sale of oysters taken from the Malabon River has been prohibited in Manila, but the law has been largely a dead letter. An American resident lately originated a plan to place these oysters on the market, and sent numerous samples to the Board of Health for examination, with a view of having the prohibition of sale removed. The examination requested was made at the government laboratories, and as a result the bacilli of cholera and of typhoid fever were found to be present on some of the specimens examined. The prohibition of the sale of the Malabon oysters has therefore not been withdrawn, and more vigorous efforts will be made to secure its enforcement.

SMALLPOX.—At present, smallpox is still on the increase, and wholesale vaccinations are going on in the provinces. Manila has now been thoroughly vaccinated, and the corps of vaccinators is being reduced. The work of vaccination was lately carried on at the rate of about eleven thousand per week. While more or less smallpox is present in Manila all the time, it is occurring in the unprotected transients constantly drifting in from the provinces. As an illustration of the kinds of diseases met with in Manila, one sanitary sub-station reported the existence in its district, on a single day, of one case of cholera, two of bubonic plague, two of smallpox and three of leprosy. Concealed cases of the latter disease are constantly being discovered in the city. They are at once segregated when found.

MALARIA.—Much malarial fever exists among the troops at certain military stations, and a general order has been issued directing the precautions to be taken against its further spread, through protection against the mosquito and the destruction of the latter wherever practicable. It is reported that an army surgeon, at a post where both American and native troops were stationed, made systematic blood examinations of all the men of the Filipino organizations, and found the malarial parasite present in the peripheral circulation in 19% of apparently healthy men, who presented no clinical symptoms whatever of the disease. He concludes from this that the native possesses a certain resistance to the malarial toxin, and that the existence of such latent infections is a strong factor in the spread of malarial fevers of a severe type among the American soldiers stationed with native troops.

RECORD OF MORTALITY FOR THE WEEK ENDING SATURDAY, APRIL 25, 1903.

| CITIES. | Population Estimated, 1903. | Reported deaths in each. | Deaths under five years. | Percentage of deaths from | | | | |
|-------------------|--------------------------------|-----------------------------|-----------------------------|---------------------------|-------------------------|--------------------------|--------------------|-------------------|

| Plymouth . . . | 10,730 | — | — | — | — | — | — | — |

Deaths reported, 3,659; under five years of age, 1,021; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 836, acute lung diseases 596, consumption 429, scarlet fever 50, whooping cough 43, cerebrospinal meningitis 5, smallpox 5, erysipelas 4, measles 40, typhoid fever 60, puerperal fever 13, diarrheal diseases 84, diphtheria and croup 92.

From whooping cough, New York 8, Chicago 7, Philadelphia 10, Baltimore 1, Pittsburg 2, Providence 4, Boston 6, and Cambridge, Lawrence, New Bedford, Springfield and Haverhill 1 each. From erysipelas, Chicago 3, Baltimore 1. From smallpox, Chicago 2, Philadelphia 1, Pittsburg 2.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending April 11 the death-rate was 15.6. Deaths reported, 4,510; acute diseases of the respiratory organs (London) 234, whooping cough 125, diphtheria 53, measles 139, smallpox 8, scarlet fever 43.

The death-rate ranged from 8.0 in Hornsey to 24.3 in Wigan; London 15.2, West Ham 13.7, Brighton 12.9, Portsmouth 13.9, Southampton 9.5, Plymouth 14.0, Bristol 12.2, Birmingham 16.2, Leicester 14.0, Nottingham 16.3, Bolton 16.8, Manchester 18.5, Salford 16.8, Bradford 15.3, Leeds 16.9, Hull 18.2, Newcastle-on-Tyne 17.8, Cardiff 14.5, Rhondda 20.9, Liverpool 18.8, Sunderland 18.8.

METEOROLOGICAL RECORD.

For the week ending April 25, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

| DATE | Ba-rom-eter. | Ther-mometer. | | Relative humidity. | | Direction of wind. | | Velocity of wind. | | We'th'r * | | Rainfall in inches. | | |

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING MAY 2, 1903.

T. C. WALTON, medical director, retired. Ordered to duty as senior member of a board of officers at the Naval Academy.

G. T. SMITH, surgeon. Ordered to duty as a member of a board of officers at the Naval Academy.

M. V. STONE, assistant surgeon. Granted sick leave for three months.

M. W. BAKER, assistant surgeon. Ordered to duty as member and recorder of a board of officers and the Naval Academy.

R. B. WILLIAMS, assistant surgeon. Detached from the "Decatur" and ordered to the "Chauncey."

J. H. HOLLOWAY, assistant surgeon. Detached from the "Franklin" and ordered home to wait orders.

E. J. GROW, passed assistant surgeon. When discharged from treatment at the Naval Hospital, Mare Island, Cal., ordered to duty at that Hospital.

C. G. SMITH, assistant surgeon. Detached from the "Marlatta" and ordered to the "Newport."

SOCIETY NOTICES.

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS. — The Congress of American Physicians and Surgeons will hold its triennial meeting at Washington, D. C., May 12, 13 and 14. The constituent societies of which the congress is composed will also have their sessions at the same time.

APPOINTMENTS.

HARVARD MEDICAL SCHOOL. — The following appointments have been made at the Harvard Medical School: EDWARD HICKLING BRADFORD, M.D., Professor of Orthopedic Surgery; MAURICE HOWE RICHARDSON, M.D., Professor of Clinical Surgery, to serve from Sept. 1, 1903; HERBERT LESLIE BURRELL, M.D., Professor of Clinical Surgery.

BOSTON CITY HOSPITAL. — At a meeting of the Trustees of the Boston City Hospital, held April 15, the following appointments were made:

DR. JOHN N. COOLIDGE was appointed Medical Registrar.

The resignation of DR. GEORGE A. LELAND as Assistant to the Surgeons for Diseases of the Throat was accepted, and he was appointed to the position of Visiting Aural Surgeon.

BOOKS AND PAMPHLETS RECEIVED.

Twenty-sixth Annual Report of the Board of Health of the State of New Jersey, 1902. Trenton, N. J.: J. L. Murphy, Publishing Co.

The Medical and Surgical Uses of Electricity, including the X-ray, Finsen Light, Vibratory Therapeutics, and High-frequency Currents. By A. D. Rockwell, A.M., M.D. New Edition. Illustrated. New York: E. B. Treat & Co. 1903.

Indications générales du traitement dans le pied-bot varus-quin congénital. By A. Broca, M.D., Chirurgien de l'hôpital Tenon. 1903.

An Inquiry into the Causes of the Recent Epidemic of Typhoid Fever in Chicago, made by residents of Hull House. Published by City Homes Association of Chicago. 1903.

Tuberculosis. By Norman Bridge, A.M., M.D. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

Medico-Chirurgical Transactions published by the Royal Medical and Chirurgical Society of London. Vol. LXXXV (Second Series, Vol. LXVII). Illustrated. London: Longmans, Green & Co. 1902.

The Care of the Baby, a Manual for Mothers and Nurses, containing Practical Directions for the Management of Infancy and Childhood in Health and in Disease. By J. P. Crozer Griffith, M.D. Third edition. Thoroughly revised. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

Congress of American Physicians and Surgeons. A Review of 720 Laparotomies for Gall-Stones with Special Consideration of 90 Cases of Drainage of the Hepatic Duct. By Prof. Hans Kehr. Translated at the request of the author by Max Z. Stern, M.D. Reprint.

Legislation Requirements for Registration of Vital Statistics. The Necessity for Uniform Laws, Methods and Forms. Washington: United States Census Office. 1903.

Practical Registration Methods. The Standard Certificate of Death. Suggestions as to its Use and Treatment. Forms of Permanent Records. Information for Local Registrars. Washington: United States Census Office. 1903.

Relation of Physicians to Mortality Statistics. The International Classification of Causes of Death as Adopted by the United States Census Office and Approved by the American Public Health Association. Washington: United States Census Office. 1903.

Medical Education in Vital Statistics. Instruction of Medical Students in Registration Methods, etc. Washington: United States Census Office. 1903.

Manual of International Classification of Causes of Death. Washington: United States Census Office. 1902.

Pneumonia. The New "Captain of the Men of Death"; Its Increasing Prevalence and the Necessity of Methods for its Restriction. By Arthur R. Reynolds, M.D. Chicago. Reprint. 1903.

A Manual of Medical Jurisprudence, Insanity and Toxicology. By Henry C. Chapman, M.D. Third edition. Thoroughly revised. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

A Text-Book of Legal Medicine and Toxicology. Edited by Frederick Peterson, M.D., and Walter S. Haines, M.D. In two volumes, Vol. I. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

Practical Points in Nursing for Nurses in Private Practice, with an Appendix containing rules for feeding the sick; recipes for invalid foods and beverages; weights for measures; dose list; and a full glossary of medical terms and nursing treatment. By Emily A. M. Stoney. Third edition. Thoroughly revised. Illustrated. Philadelphia, New York, London: W. B. Saunders & Co. 1903.

Handbook of Climatology. By Dr. Julius Hann. Part 1. General Climatology. Translated with the author's permission from the second revised and enlarged German Edition, with additional references and notes, by Robert de Courcy Ward. New York: The Macmillan Company. 1903.

Observations upon Leprosy Occurring in Japan, Iceland and Norway. By Judson Daland, M.D., of Philadelphia. Reprint. 1903.

Meniere's Disease, with Report of a Case. By James M. Brown, M.D., and Judson Daland, M.D., of Philadelphia. Reprint. 1898.

Report of the Commissioner of Education for the Year 1900-1901. Vol. II.

The Office Treatment of Rectal Diseases Explained and Simplified, being an Exposition of the Treatment of all those Diseases, both Medical and Surgical, of the Rectum, Anus, and Sigmoid Flexure, the Cure of which may be accomplished without Surgical Anesthesia. By Rufus D. Mason, M.D. Illustrated. Second edition. Lincoln, Nebraska: The Review Press. 1902.

Muco-membranous Enterocolitis Symptoms, Complications, Etiology and Treatment. By Maurice de Langenhagen, M.D. London: J. and A. Churchill. 1903.

Anatomy of the Brain and Spinal Cord, with Special Reference to the Grouping and Chaining of Neurones into Conduction Paths. For Students and Practitioners. By Harris E. Santee, M.D., Ph.D. With a preface by William T. Eckley, M.D. Third Edition, revised and enlarged. Illustrated. Chicago: E. H. Colegrove. 1903.

Addresses.

THE DUTIES AND RESPONSIBILITIES OF TRUSTEES OF PUBLIC MEDICAL INSTITUTIONS.¹

THE PRESIDENTIAL ADDRESS AT THE SIXTH CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS, WASHINGTON, MAY 12, 1903.

W. W. KEEN, M.D., LL.D., F.R.C.S. (HON.), OF PHILADELPHIA,
Professor of the Principles of Surgery and of Clinical Surgery,
Jefferson Medical College, Philadelphia.

THE value of occasional and stated gatherings of the principal leaders of medical thought in the various special departments is acknowledged by all. Certainly those who have attended this Congress, now held for the sixth time, have felt its broadening influence. We are all apt to become narrow when we are devoted heart and soul to one specialty, be it medicine, surgery, physiology, ophthalmology or any other. When we meet nearly all of the more prominent men in cognate interrelated branches of medicine in Washington every third year, we are sure to find that there are as interesting and as important questions in other specialties as there are in our own; and, moreover, we are sure to find that there are men of as acute intelligence, wide reading and original thought in other than our own departments whom it is our pleasure to meet, and whose acquaintance becomes not only valuable for what we find them to be, but because of the stimulus that they give to our own thoughts.

Ordinarily the presidential address has been devoted to some special professional topic. My first idea was to select such a subject for tonight, but as I was absent from the country when I received the very highly appreciated notice of my selection, I asked the members of the executive committee for suggestions, being sure that their united judgment would be better than my own. I was very glad when they proposed the topic upon which I shall address you, partly because it is different from the usual type of such addresses, and partly because it seems to me appropriate to the present time. I shall, therefore, give the time at my disposal to presenting to you some thoughts on "The Duties and Responsibilities of Trustees of Public Medical Institutions."

Before entering upon my topic I beg to state explicitly that what I may say is offered in no spirit of unfriendly criticism, but only by way of friendly suggestion. I have been too long and too intimately associated with scores of such trustees not to know that they are almost without exception generous, self-sacrificing, giving of their time and money and thoughtful care without stint, and often sacrificing personal convenience and comfort for the good of the college or hospital which they so faithfully serve. Anxious to discharge their trust to the best of their ability, I am sure they will accept these suggestions, the fruit of forty years of personal service as teacher and a hospital surgeon, in the same friendly spirit in which they are offered.

There are two such classes of institutions to be considered: (1) Medical colleges, and (2) hospitals, whether they be connected with medical schools or not.

¹ From advance sheets of the Sixth Volume Transactions of the Congress of American Physicians and Surgeons, 1903.

There is, it is true, a third class of trustees for a wholly new kind of medical institution which has arisen as a modern Minerva Medica, born full-armed for the fray. Of this class we have as yet but a single example — the Rockefeller Institute for Medical Research. Akin to it are laboratories for special investigations, such as the two cancer laboratories in Buffalo and Boston. But the Rockefeller Institute is so recent, and its scope at present necessarily so undetermined, that I would not venture to consider the duties of these trustees, and I am sure their responsibilities are adequately felt by them. Moreover, their admirable selection of a director for the institution is the best pledge of a future wise administration. I heartily congratulate the profession and America upon the establishment of so peculiarly useful an institute. Its founder has wisely left its work unhampered saving as to its general purpose, and the whole world, and especially the United States, will soon be his debtor for researches and discoveries that will abridge or even abolish some diseases, shorten sickness, prolong life and add enormously to the sum of human happiness. Could any man of wealth by any possible gift win for himself a higher reward or a happier recollection when he faces the future world?

Though not a medical institution, I cannot refrain also at this point from expressing not only for myself, but for you, our hearty appreciation of what the Carnegie Institution has done for medicine in the re-establishment of the *Index Medicus*. This publication is essentially and peculiarly American in origin, but its usefulness is world-wide. It aids alike an author in Japan or in India, in Europe or America. It is one of the best and wisest undertakings of this lusty educational giant. But to ensure the permanent publication of the *Index Medicus* the profession must show that it really values this generous gift. Unless the *Index* finds a hearty support in the profession abroad and especially at home, we can hardly expect the continuance of this unique and invaluable publication. May I earnestly ask, therefore, of this audience of the chief medical authors of the United States that each one will demonstrate his appreciation by an immediate subscription to the *Index Medicus*?

There are some matters common both to the medical college and the hospital which may be considered together. The most important of all these is the cordial and hearty co-operation of the medical men connected with the college or hospital and the boards of trustees. In order to ensure this the members of each body must be acquainted with each other. I have known of instances in which if a professor in the medical school ventured to suggest any changes as to its management, or even to state his opinion as to the qualifications of a candidate for a vacant professorship, his suggestions were resented as an interference instead of being welcomed as a means of valuable information. I take it for granted that we should not offer such suggestions after the fashion of a partisan either of a man or a measure, for the advancement of a friend or to the disadvantage of an enemy, but solely for the good of the institution with which we are connected. He who would endeavor to foist a friend upon an institution *because* he is his

friend, and in spite of the fact that a rival is the abler man and better fitted for the position, is just as false to his duty, to his college or to his hospital, as the trustee who would vote for the less desirable man on the ground of personal friendship, or of association in some society, church or similar other body. Of all these influences, that arising from membership in the same religious body is, I fear, the most frequent and yet most absolutely indefensible. What one's theological opinions are has no more to do with his qualifications for a professional or hospital appointment than his opinions on protection as against free trade, or whether Bacon or Shakespeare wrote "Hamlet."

I have always honored one of a board of trustees, who was an old personal friend of my father's and who had known me from boyhood, yet who in my early professional career, when I asked for his vote for an important hospital appointment, had the manly courage to tell me that he thought a rival, who was older and more experienced, was the better man for the place and that he should, accordingly, vote for him and not for me. I confess it was at the time a bitter disappointment to me, but I never had so high an opinion of my father's friend as after he denied me his vote.

There should be, in my opinion, but two questions asked in considering the election of either a professor or a hospital physician or surgeon. First, which one of the candidates for the place has the best qualifications from the medical point of view? This should include not only his scientific knowledge, but his ability practically to impart or to apply that knowledge. Secondly, are his personal qualifications and character such as to make him a desirable incumbent of the position? It must be remembered that a man may be scientifically and practically an extremely able man, but of such a quarrelsome disposition, or the unfortunate possessor of some other similar personal disqualification, as to make him a most undesirable member of a staff. The personal equation may be quite as important as the scientific qualification. Of course his personal moral character should be above reproach. To place a drunkard or a libertine in a position of so much responsibility and influence is to abuse a trust. No patient should be confided to the care of such a man and still more no such man should be made an instructor of young men, upon whom his influence would be most disastrous.

It is often extremely difficult for a layman to reach a correct conclusion as to the qualifications of medical men for college or hospital appointments, because of the confident, yet conflicting, statements of their friends. But there is apt to be a certain clear partisanship in such statements which betrays the purpose of the speaker. Especially will this be so if he advocates the election of A or B on the lower grounds of friendship, social position, or for other similar motives. The man who is advocating the best man because he is the best man has the stamp of sincerity upon every word.

Perhaps the most striking example I can adduce of such an unfortunate misjudgment is Dr. S. Weir Mitchell, who was denied a professorship in both the medical institutions of his native city, thus depriving them of the most brilliant medical genius

that America has produced within my personal recollection. For him it is now a matter of indifference, and for American literature it has been a gain. But for medicine, and especially for physiology, it was an immense loss. Both of his rivals were estimable, worthy gentlemen, who held an honorable position in the profession, it is true, but Mitchell is a genius. "Eclipse was first; the rest were nowhere."

One of the best methods of bringing the medical board and the board of trustees into more intimate contact would be to have the dean or a committee of the faculty, or, in a hospital, if the staff is not too large, the whole staff invited to the meetings of the board. Here I can speak from personal experience. At the Orthopedic Hospital and Infirmary for Nervous Diseases in Philadelphia, there are three surgeons and three physicians. These members of the medical staff are invited to meet with the board of managers at each monthly meeting, excepting the annual meeting, when the medical staff is elected. They are free to express their opinions on any topic relating to the management of the hospital to which their judgment may contribute something of value, but when a decision is taken they have no vote. It is purely in an advisory capacity and for the purpose of giving and receiving information that they are present. The plan works exceedingly well. When economy is necessary in the hospital, the staff is fully acquainted with the fact and can co-operate with the trustees; when expenses have run up from carelessness in the wasteful use of dressings or appliances, a halt is called; when, alas, very rarely, the treasurer is all smiles, and plans for the extension of the hospital or the installation of some new addition to the plant are contemplated, their knowledge as to the necessity, for instance, of a hydrotherapeutic or an x-ray plant, or a new operating room, is the greatest possible value. Nothing but good, in my opinion, can come from such personal co-operation.

One of the difficult questions which boards of trustees have to face is whether there shall be a fixed age at which a college professor or a hospital physician or surgeon shall retire from the active duties of his post. I firmly believe that they should fix such a retiring age in the interest of the students and the patients. As age advances, a man's opinions and his practice become "as petrified as his arteries." He is incapable of constant study, of adding to his knowledge or of keeping up with the feverish strides of medicine. He ought then to be relieved of his cares and his duties. If no rule exists, he is allowed to continue his inefficient or even disastrous work, or by some harsh suggestion is compelled to give place to another more competent man. A rule is a condition accepted when he is appointed; and just as in the army and navy, when an officer reaches sixty-four or sixty-two years of age he is retired on reduced pay, and because it is a rule he does not feel hurt or humiliated, so in a college or a hospital, when time and the rule bring us to the period when we must gracefully retire, no one's reputation is injured or his feelings lacerated.

I have ascertained that the following rules are in force in some of the larger institutions:

At Harvard the age when a professor may request

to be retired is sixty, provided he has been in the service of the university for twenty years, with a reduced pay ranging from one-third to two-thirds of his salary. At sixty-six he may be retired by the president and fellows partly or wholly. The details of the plan are admirably arranged.

At Chicago, while no plan is yet in force, largely, presume, because of its recent establishment on the present basis, such a plan will soon be made operative.

At Columbia the retiring age, after fifteen years of service, is sixty-five, either at the request of the professor or upon motion of the trustees, and on half pay.

At Yale the retiring age is sixty-five, after twenty-five years of service, and on half pay, but the retirement is not compulsory. It will probably be made compulsory before long.

At Cornell the retiring age is seventy, but the Pension Fund will not be available until 1914. The retiring pension will then be \$1,500.

At the University of Pennsylvania and at Johns Hopkins no retiring age is fixed.

The only hospitals I know of in which a retiring age is fixed are the Massachusetts General Hospital and the Boston City Hospital. At the former the compulsory retiring age of the surgeons is sixty-five, and of the physicians sixty-five. At the Boston City Hospital the visiting surgeons are retired at sixty-five, but the physicians, gynecologists and the other medical officers continue in service definitely—a very curious anomaly.

These varying but in the main identical provisions, when any exist, show the trend of thought and practice. They generally apply to the medical department, except that in case a professor is engaged in the practice of his profession and so has a private income, the provision for continuing a portion of his salary does not apply. This is right and fair. Of course, in all hospitals where there are no salaries, no provision as to reduced salary would obtain.

The point I wish to emphasize is, however, that the age limit (which in my opinion should be sixty-five) should be *compulsory*, and so not be invidious in any even case. It will be objected that not a few men are in full intellectual and physical vigor at sixty-five, and it will be a detriment to the institution to lose their services when their ripe experience and admirable teaching are most desirable. I admit it. But for every one such case of harm done by compelling a man to stop, there are a score of instances of men who are doing vast injury by their inefficiency. Moreover, in the very few cases in which it might be allowable, as boards of trustees make it, they can unmake them, and in special cases they could pay a graceful compliment and preserve the institution their exceptional men by extending the limit to seventy. In no case can I think it wise to go beyond this limit.

In some of the universities I have quoted a sabbatical year of rest or study is allowed a professor. He is put upon half pay, and his place is filled by a temporary substitute, who receives the other half of his salary. I believe that in present conditions this should not be applied to medical faculties, for nearly all of the professors are in active practice and take sufficiently long summer holidays. These

latter are often spent in observation and study abroad,—a most useful and remunerative employment of a holiday,—and serve the purpose of the sabbatical year for men whose entire time is given to their teaching. In hospitals it certainly should not apply.

One of the recurring questions in hospital and college management is whether there should be a certain number of doctors on the board. I know that there is a wide diversity of opinion upon this point. My own belief is that a small proportion of well-chosen medical men is a distinct advantage in such boards of trustees. I have said a "small proportion," for it should not be, I think, larger than probably 20%; and I also said "well chosen;" that is, they should be men of large mental caliber and executive ability. It should be distinctly understood, if not indeed absolutely expressed, in institutions in large cities at least, that any physician or surgeon placed upon such a board should never be eligible, even by resignation from the board, for a position on the faculty or the medical staff. In small towns the lack of suitable persons for hospital trustees and members of the hospital staff might make it desirable not to institute such a rule.

Moreover, such medical men should be selected for trustees as by their mental training, social relations and personal character would be, so far as it is possible for human nature to realize such a position, absolutely free from influences arising from personal jealousy or professional bias. If it were a social club, it would be perfectly proper to vote against a man because he is personally distasteful; but where it is a scientific body, responsible for the education of large numbers of young men and for the care of still larger numbers of hospital patients among the poor, even if a candidate were personally unfriendly I should vote for his election if he were the man best fitted for the place.

Turning now to the duties and responsibilities peculiar to trustees of hospitals, let me point out the objects of a hospital.

First, the care and the cure of the sick and injured; secondly, the education of medical men and medical students; and thirdly, the promotion of knowledge, which, in turn, will inure all over the world to the more speedy and certain cure of the sick and injured, and so be of the greatest benefit to humanity.

In order to accomplish these three purposes it is necessary that the hospital shall have sufficient funds to purchase ground, erect buildings and provide a thorough material equipment. It is a great pleasure to me, as to you also, to note that throughout the length and breadth of the land the medical and surgical staff never tax the always inadequate resources of hospitals for any remuneration. They serve without pay, they give ungrudgingly and freely day and night to the poor, often for many years, their time and skill, without ever a thought of any money reward. Their reward comes from increased knowledge and skill, and the daily blessing invoked of heaven, often lisped in children's prayers or breathed in mothers' benisons, which pass not unheeded by the recording angel.

But, as I have pointed out elsewhere, instead of receiving any pay, they give to hospitals. The mere money value of this daily gift of the profes-

sion to the poor amounts to an enormous sum. The value of the professional services of the staff of the Jefferson Medical College Hospital, a single hospital in a single city, on a moderate basis of fees, I found was more than half a million dollars annually. The millions upon millions of money given in that most self-sacrificing form—personal service—by the entire profession all over the United States, and I might add with still further pride, all over the world, is simply incalculable. The Gideon Grays and Weellum MacLures are not found only in Scotland or at the countryside. They are even more plentiful in the slums of our great cities, giving of their time, their skill, and what is more, their hearts, their lives, themselves, to the service of humanity.

Trustees sometimes seem to take it for granted that their duties are ended when they have done two things: begged or given and safely invested the necessary funds, and then elected the staff. To my mind, their duties do not by any means end at this point. They should see to it that the resources of the hospital are utilized to the utmost in doing the largest good.

Let us see now how the objects of a hospital, as I have stated them, can be realized. The first object is the care and cure of the patients. But the cure of any individual patient is not the "be all and the end all" of a hospital. His cure must be a means of larger vision to the doctor, who will thus be better fitted to care for future similar cases. Even his death, if he cannot be cured, should minister to the increasing knowledge and skill of the doctor, so that he may be able to snatch future victory from present defeat.

The second—the training of doctors and students—is frequently carried out, but sometimes even objected to. There are three classes of doctors who are trained by a hospital: first, the staff of the hospital itself. I have lived through the period of the establishment of hospitals in many of the smaller cities and towns, and in some cases even villages in this country, for it was a rare thing in my early professional life for any except the larger cities to have hospitals. The moment that a hospital is established with its medical and surgical staff, that moment a new era has dawned on the *community* in which the hospital is established. More careful methods are introduced, greater cleanliness is observed, hygienic conditions are bettered, laboratory methods are inevitably introduced in time. Even if the old-timers who graduated years before our modern laboratory methods were adopted do not care for them or cannot use them, the young fellows who come fresh from our medical schools and serve as residents, and even the nurses graduated from our training schools, finally shame the older ones into better ways and greater exactness, not only in the hospital, but in their private work as well.

As a consequence of the establishment of these hospitals and the added skill and training of the local physicians and surgeons, the character of the consultations of the physicians and surgeons of our great medical centers has been greatly modified. The really simple cases, such as hydrocele and small tumors (and even large ones), clubfoot, harelip, etc., which used to be sent to city consul-

tants, are now successfully operated on by the local surgeons, and only the more difficult, serious or complicated cases are sent to the cities. This is a great advantage to the patient, whose good is the first consideration, and to the local medical men; and though seemingly a serious loss to the city consultant, it is in the end an advantage, as he must prove his better metal in the higher scientific fields and be, as well as seem to be, the better man.

Moreover, the trustees of every hospital should see to it that a good library and laboratory are provided. Insensibly the staff will read more and more. A single restless progressive spirit, even though it be a young interne calling attention to this case and to that, in one journal or another, will compel the rest of the staff to read in spite of themselves. It is absolutely clear that a laboratory with modern equipment for bacteriological, pathological and chemical research in its examination of tumors, of the urine, the sputum, the feces, the blood, the pus and other fluids from wounds, etc., is a necessity in every hospital. Even many of our smaller hospitals are equipped with microscope and reagents if not with a complete bacteriological outfit, which nowadays is inexpensive and imperative. All of this raises the intellectual and professional standard of the staff. I venture to say that no town of 20,000 people can afford to be without its hospital for the sake of its *own citizens*, utterly irrespective of the good it does to the poor who are treated in its wards. It must be established in the interest of the *well-to-do citizens* and their families, so that they may secure better-equipped doctors for themselves as well as for the patients in their hospital. Self-interest, therefore, will compel every community to establish its hospital, even if charitable motives had no influence.

Again, the trustees of all hospitals of any size should establish a training school for nurses. Only those who, like myself, have lived in the period before such training schools were established, can appreciate the vast improvement effected in a hospital by this change. To replace the former ignorant, untrained attendants by "trained nurses whose jaunty caps and pretty uniforms and often winsome faces, almost make one half wish to be sick, and when one is sick, half loath to be well," is not only a boon to the patients but to the doctors as well. The intelligent, well-trained nurse, who is on the alert to observe every important change of symptoms and who will keep accurate bedside notes, is the doctor's right hand. Not a few patients who would otherwise lose heart and hope are, one may say, lured back to health and happiness by the tactful attentions and restful but efficient care of such a nurse. The community of the well-to-do also are benefited, because the hospital provides them with skilled nurses in their homes when they are so unfortunate as to be compelled to remain there instead of going to the hospital.

The old repugnance to entering a hospital when sick or when an operation is demanded is rapidly fading away. The immense advantages of a good hospital over the most luxurious home are now acknowledged on all hands. The poorest patient in a hospital is better cared for, his case more carefully investigated by bacteriological, chemical and clinical methods in a hospital, than are the well-to-do in

their own homes. Indeed, wise surgeons, except in cases of emergency, now very properly refuse to do operations in homes instead of in hospitals. In many instances lives that would be lost in homes are saved in hospitals, where the many and complex modern appliances for every surgical emergency are provided.

The hospitals in direct or indirect connection with medical schools, however, do a far larger work than merely the training of their own staffs of doctors. They train three other classes of doctors: First, the undergraduates who are aspiring to the degree; secondly, graduate physicians who spend a certain amount of time in the hospitals either as internes or temporary students refurbishing their professional knowledge; and thirdly, experts in certain branches of medicine and surgery.

The undergraduates are taught first in the general clinics, where to some extent they learn both by didactic instruction and by seeing the patients, hearing their histories and witnessing the institution of proper treatment by prescriptions, by regimen, if necessary, by surgical operation. This is of great value, particularly in the more important cases, and especially, for I speak now as a surgeon, important operations. It is often objected that students see nothing in large clinics. To some extent this holds good; but no student can look on an operation when the jugular vein or the lateral sinus is torn, the pleural cavity opened, the bowel perforated, or other of the great emergencies of surgery occur, and fail to be impressed by the coolness of the operator, the carefully explained methods adopted for remedying the mischief, and the various devices used to save life, all of which hereafter will be used by him when similar emergencies may occur. Yet far more important than the public clinics are the smaller clinics held with classes of ten to twenty men each, when under an experienced teacher the absolute work of the clinic is divided among the various students in turn, watching the pulse and the respiration, giving an anesthetic, assisting actively in operations, percussing the chest, palpating the abdomen, determining inequalities of the surface or the varying density of underlying organs. Here is the real forum in which our modern medical student acquires his skill. In many cases visits in the ward itself are made, and to a small group around the bedside the physician or surgeon will point out the phenomena to be recorded, the need for the examination of the blood, the results of bacteriological cultures, the facts discovered by the microscope or the chemical reagent. By the Socratic method also, he will reveal to the student the imperfection of his knowledge, call out — educate — his powers of observation, of reasoning; stimulate his thought, and give him an impetus which will last throughout life. Who that has "walked the hospitals" with a Skoda, a Trousseau, a Nélaton, a Costa or a Mitchell can ever forget their teacher?

It is sometimes objected by those who are not familiar with the actual facts, and especially by trustees, that this method of actual bedside instruction does harm to the sick. I speak after an experience of nearly forty years as a surgeon to a half-dozen hospitals, and can confidently say that I have never known a *single patient* injured or his

chances of recovery lessened by such teaching. Of course, the physician or surgeon uses common sense. He would not allow a number of men to palpate the abdomen of a patient with peritonitis, or move an acutely inflamed joint, nor would the physician allow a patient with pneumonia to have the chest unduly exposed, or a typhoid fever patient disturbed if his condition was such that it would be inadvisable. But such cases are the exception. In fact, many of you are familiar with patients who have responded to repeated percussion by members of such a class by prompt recovery, attributed by the patient to the supposed medication of percussion. Moreover, it is by this actual practice only that the student acquires the necessary skill in the use of modern instruments of precision, such as the stethoscope, the laryngoscope, the esthesiometer, the sphygmomanometer, the various specula. Here he learns when to make blood counts, how to make histories, arrive at the actual facts by skillful cross-questioning, note the varying symptoms and physical signs of a case, determine the need for laboratory investigations, all under the guidance of skilled observers, who will point out his errors, encourage his queries and stimulate his thought.

Moreover, trustees may overlook one important advantage of a teaching hospital. Who will be least slovenly and careless in his duties, he who prescribes in the solitude of the sick chamber, and operates with two or three assistants only, or he whose every movement is eagerly watched by hundreds of eyes, alert to detect every false step, the omission of an important clinical laboratory investigation, the neglect of the careful examination of the back as well as of the front of the chest, the failure to detect any important physical sign or symptom? Who will be most certain to keep up with the progress of medical science, he who works alone with no one to discover his ignorance; or he who is surrounded by a lot of bright young fellows who have read the last *Lancet* or the newest *Annals of Surgery*, and can trip him up if he is not abreast of the times? I always feel at the Jefferson Hospital as if I were on the run with a pack of lively dogs at my heels. I cannot afford to have the youngsters familiar with operations, means of investigations or newer methods of treatment of which I am ignorant. I must perforce study, read, catalogue and remember; or give place to others who will. Students are the best whip and spur I know.

Of the value of training graduates in postgraduate work I need scarcely speak, to this audience at least. The doctor who graduated five, ten or fifteen years ago comes to our great centers of medical education and renews his youth at the fountain of knowledge. He learns the use of all the new instruments, sees new methods of operation, new methods of treatment, new means of diagnosis, and goes home an enormously better equipped man.

The trustees should see that the staff does not become fossilized by following the same ancient local methods from year to year, but should encourage them to visit other hospitals, see other men operate, hear other men discourse on the latest methods of investigation, and then import into their own hospitals all the good found elsewhere.

I learn a deal by such frequent visits to the clinics of my brother surgeons, and if one who has grown gray in the service can thus learn, surely the younger men can do so. When we are too old to learn we are too old to remain on a hospital staff.

I do not know anything which has more impressed upon me the enormously rapid progress which surgery is making than a recent experience. I was absent from this country for almost a year and a half. In that time circumstances were such that I saw almost no medical journals and but few doctors. I have been home now eight months, and even with incessant work I have not yet caught up, so rapid has been the progress of surgery in this short time. Had I been absent for five years, verily I should have been a "back number," and never could have caught up at all.

In his very excellent presidential address before the Association of American Physicians in 1901, Professor Welch made a plea for hospitals to afford "the requisite opportunities to young men who aim at the higher careers in clinical medicine and surgery." He called attention to the fact that in our bacteriological, pathological and anatomical laboratories the opportunities, though still too few, were reasonably good, and in a few places exceptionally good, for the training of young men for positions as teachers of anatomy, pathology and bacteriology. Any young man in these departments who by good hard work makes for himself a name is fairly sure, before long, of being called to some important post as a professor, director of a laboratory or some similar position. But the facilities for work in clinical medicine and clinical surgery are far more restricted, since opportunities for both the exercise of their clinical skill are less frequently open to them and the possibility of combined physiological, pathological, bacteriological and anatomical research along with their clinical work is but scantily provided for. This plea is reinforced by the recent paper of Sir Michael Foster (*Nineteenth Century*, January, 1901, p. 57). These special graduates, bright young men, determined to devote themselves to one or another department of medicine or surgery, are the men who bring honor to the school at which they obtain their training, and are invaluable to the community. They are the future Jenners, Pasteurs, Virchows, Listers, DaCostas and Grosses, and our hospitals should provide for these exceptional men exceptional facilities.

The third object of a hospital is the promotion of knowledge, and so, fourthly, the good of humanity. Physicians and surgeons engaged only in private practice do not generally keep notes of their cases, and rarely publish important contributions to knowledge. I find in 100 books taken consecutively in my library that 85 were written by hospital men and only 15 by authors not connected with any hospital so far as was indicated on the title page.

In order that proper investigations may go on, trustees should enforce a permanent record of all the cases treated in the hospital, properly indexed, from which the staff may derive their data for papers and books. Each large hospital should have its pathological resident as well as the clinical residents in that various wards, so the postmortem

records shall be well kept, pathological, bacteriological, and chemical investigations of various secretions, or blood counts, etc., shall be properly made and permanently recorded in such a manner as to be accessible.

It is too often the case that trustees, as I have said, regard their duties and responsibilities at an end when they have taken care of the funds and elected the staff. They may say that after all this is their real duty, and that all that I have advocated is medical and surgical, and the responsibility for it should devolve on the staff and not on the trustees. I do not take so narrow a view of the duties of trustees. When they have elected a physician or surgeon, if he neglects his duty, it is their business to displace him and fill his place with another man who will attend to his duty, and the duties that I have indicated pertaining to the increase of knowledge as well as of its diffusion are quite as much within their province as it is to see that the funds are invested to the best advantage. The intellectual funds as well as the invested funds must bring in good dividends.

If trustees and staff work together for such a purpose and in such a manner they will create an ideal hospital, which will do more good to the patients than any other type of hospital. It will attract the best physicians and surgeons in every community, will acquire the best reputation, not only local, but it well may be national, and do the most for the good of science and the benefit of humanity.

It may be said that this is an unduly strenuous view of the duties of trustees, that in our fathers' day and in our own earlier lives no such conditions existed or were contemplated. "I need hardly ask a body like this," said President Roosevelt in addressing the Methodists assembled in council, "to remember that the greatness of the fathers becomes to the children a shameful thing if they use it only as an excuse for inaction instead of as a spur to effort for noble aims. . . . The instruments with which and the surroundings in which we work have changed immeasurably from what they were in the days when the rough backwoods preachers ministered to the moral and spiritual needs of their rough backwoods congregations. But if we are to succeed, the spirit in which we do our work must be the same as the spirit in which they did theirs."

Moreover, we must remember that "the world-field into which all nations are coming in free competition by the historical movement to which all narrower policies must sooner or later yield, will be commanded by those races which, in addition to native energy and sagacity, bring the resources of scientific investigation and of thorough education." The international race for the leadership of the world is just as strenuous and intense in medicine as it is in commerce. If we are going to join the race and win the prize there must be the highest development of American education at the top. The best men must be pushed to the front, and ample opportunities for growth, for investigation and for original research must be provided. Never has there been so large an opportunity for the man of large ideas, complete education and indomitable energy and purpose as there is to-day. The world is waiting, looking, longing for him, and will cry "Make room!" for him when he is found.

In the hands of the trustees of our colleges and hospitals are the money and the opportunity for developing such men. If the right spirit pervades both trustees and medical faculties and hospital staffs, then it will be but a short time before America will lead the world in medicine as she now does in commerce.

Will the profession rise to the level of their great opportunity? Yea, verily they will! Never yet have they been wanting when the emergency arose; not only the emergency of labor, but also the emergency of danger.

In Russia the common soldier counts for little. Yet in Vladikavkaz (where the Dariel Pass, — the old Portæ Caspiæ of Herodotus, — leading from the Caucasus, joins the railroad from Baku on the Caspian to Moscow) is a monument to a common soldier. At the last battle in which the Russians won the victory over Schamyl, which gave them undisputed sway over the Caucasus, this soldier blew up a mine and won the day at the cost of his own life. It was ordered that his name should never be erased from the list of his company. At every roll-call when his name is reached, the solemn answer is given, "Died in the service of his country."

In our hospitals lurk the deadly breath of diphtheria, the fatal virus of bubonic plague, of cholera, of yellow fever, of typhus fever, and the ever-present danger of blood poisoning. I have known of brother physicians who have died victims to each one of these scourges. Yet who has ever known one of our guild to shrink when danger smote him in the right hand and the left and death barred the way? As brave as the Russian soldier, ready to risk life, and, if need be, to lose it, these martyrs to duty shall never have their names stricken off the honor list, and at the last roll-call the solemn reply shall be, "Died in the service of humanity."

SOCIAL CONDITIONS IN AMERICA IN THEIR RELATION TO MEDICAL PROGRESS AND DISEASE.*

BY J. M. ANDERS, M.D., LL.D., PHILADELPHIA.

ANOTHER spacious year with its varied channels of energy and activity in medicine has closed. Whilst a faithful chronicle of the facts, data and achievements showing the progress of internal medicine for that brief period would have proved an appropriate topic, I have availed myself of the choice privilege granted by this association of selecting my theme, and purpose to consider the subject of the relation of American social conditions to the progress of medicine and disease, and the import of modern economic and professional tendencies in forecasting the immediate future.

The state of American society, founded on democratic ideals, is one in which the true function of the physician has ever been both intellectually and morally beneficent. It has ever been the fate of the medical profession, however, to have its past outgrown and stifled by the enthralling energy and life of its present, and to forget to fix its gaze on what is grand and significant in inherited associa-

tions and opportunities. Conversely, the fundamental principle of human development, to wit, that the present is quickly passing under the control of the future, which transcends an enlightened self-interest in the present, is yet to be fully realized and appreciated. In the life of our civilization the physician has constantly found himself in the presence of golden opportunities to render a service to the community, to add his private thought to the public opinion. His high calling and the stage of social development from which he has proceeded have ever invited to the development of an expanding and humane spirit. He has been, however, in many cases too closely chained to his special work. *Per contra*, the individual member of commanding worth and formidable individuality, like the Spartan and the Greek, has fortunately lent his own spirit to the genius of the great organism — the medical profession — and its higher destiny. That genius is no sluggard, and the motive of action is not the pursuit of gain or of personal aggrandizement, but an incessant advancement of our art and science and an application of the faculties to the higher interests of civilization. What is needed in medicine, from the standpoint of sociology, at the present day in America, is the true "scientific spirit clothed with human interest," to give force and direction to the means available, not only with a view to the application of science to the healing art, but also to enable our profession to find its true place in the body politic and its intrinsic importance as a factor in modern civilization.

While there are certain things and events common to all in our psychic and social development, enlightened society will grant that the larger events in American history, assuming that "the first duty of society is the preservation of life and the comfort of its units," have not been so much dominated by legislative authority and social customs as by the march of science, more particularly medical and hygienic. In a country as vast as ours, however, there could be no uniform law covering the details of results in matters medical. These have in the past, and will in the future, vary somewhat with the climate, physical conditions, degree of culture and opportunities presented by the widely separated regions. As a consequence, in displaying proportions and the practical results of scattered sections, the final adjustment of their claims only becomes perceptible and appreciable in their broader and higher generalization. The whole range of American historic data and events indicates an imperishable foundation of scientific achievement, and furthermore establishes firmly a relationship between medicine and the scientific principles underlying social conditions and phenomena that is both positive and vital. As touching the American medical history of the long past, we can see the major advances and their influence on social laws and the progress of civilization only by grouping data and established facts and applying the process of generalization to these composite phenomena. In this connection it is to be regretted that our possession of unclassified facts is increasing with uncomfortable rapidity. A comparative and historic study of the medical literature of America, taking any of the older countries as a standard of comparison, in respect to this method of generalization, can

*The Address in Medicine before the Medical Section of the American Medical Association, New Orleans, May, 1903. By the courtesy of the Journal of the Association.

scarcely prove even measurably satisfactory. Much of the history of native medicine is crude, and it were impossible to give it either crystallized or concrete form. Epoch-making discoveries and important, far-reaching scientific effort is justly the boast of the American profession. Systematic effort at a rigid classification of facts by the modern statistical method, however, has not been made, and only a partial scientific use of the ever-advancing events for the different historical periods has been attempted.

The concrete, comparative and historic method of study, which alone furnishes a proper basis for generalization and serves to point out the relations of medicine to other human activities, would ensure a wholly fresh treatment of the earlier medical annals of America. The physician in his economic or professional dealings has not followed his self-interest in comparison with his measure of enlightenment to an equal extent with men in other lines of human activity; but the fruits of his unselfish labors are, when taken collectively, presented in the form of a heterogeneous mass of details. It should be recollected that it is only the larger events, the accurately grouped facts after the method of generalization to which I have referred, that go to make up the bulk of medical history and medical law. The practical results of the method of simple generalization would show clearly the final utility of medical and sanitary knowledge in the social universe, and manifest its relation to everyday life. Obviously in a young republic like ours something must be allowed to propinquity—to nearness to a confusing and disordered mass of facts and phenomena.

It has been well said, "A landscape is beautiful because distance has reduced its chaos of details into order."

Those endeavoring to make a personal study of the medical and sanitary requirements of our insular possessions, more especially under new and changed conditions, cannot hope to gain more than a fragmentary knowledge. Much important and accurate information touching the social, climatic and medical conditions and necessities, however, is available through the Division of Insular Affairs, in the War Department at Washington. It is clearly incumbent on the organized profession of the United States to undertake studies on a larger scale than that of individual effort. Moreover, the interrelations between tropical medicine and the sciences before alluded to, that is, social and sanitary, is a question for the immediate future; thus step by step may we hope to erect a stairway that will lead to a new temple of knowledge.

The foundation for social order, education and a fair measure of self-government under military rule having been laid both in Porto Rico and the Philippines, there is presented to the profession of the United States an opportunity amounting to an obligation to carry into those new possessions the light of modern sanitary and medical science. The peoples of those islands are as clearly entitled to the benefits offered by our science and art as they are to those pertaining to their fundamental civil and personal rights, as guaranteed by the Constitution of the United States.

From the America that Cortez invaded until the

present the most treasured resource of our nation to the physician has, in a peculiar sense, been human life, and in respect to this economic principle we are, at present writing, merely following in spirit our thoughtful forebears. The medical profession never has valued life in terms employed in denomination nor by its productive power, but rather measured it from a divine and humanitarian standpoint. Certain it is that with advancing civilization there has come a higher and higher appreciation of the value of agencies intended to promote longevity and minimize disease and suffering. And this tendency to preserve human existence, apart from sentimental considerations, is born of a principle long adhered to by the medical profession, and continuously unfolding itself in the individual and in organized medical bodies. It is clear, without seeming extravagance of statement, that greater justice is done by the medical profession of America to the condition of society just pointed out than in foreign lands, since it is more thoughtful for the youth and hope of our profession. It is to the flower of that youth, with its new and hidden virtues, that we must look for disclosures in the province assigned to the higher and more complex professional bodies of the future. Modern democratic institutions, including medical schools, are in the ascending scale of civilization, infusing into our profession men who are armed with potent resources from the pedagogic world.

The present-day educational facilities and developments show an ever-increasing beneficent tendency, and the standard of qualification has passed, or is passing, beyond the stage in which there is a mere desire to acquire an elemental knowledge of disease and its treatment in this country; a new character and a new vital and moral force is happily presuming to show itself in public action for the benefit of mankind. This genius stands ready to kindle its fires and materially aid in offering the means of human welfare and the revelation of new truths.

An appreciation of this fact by professional bodies is necessary in respect of the future; for medical societies organized to obtain the highest potency must compete successfully with other societies, or they will vanish from view in the stress of social and scientific evolution.

But though the obscure rival of the Goddess of Minerva, who had broken the loom of Arachne in her jealousy, executed wonderful tasks by her unaided strength, in the process of progress towards higher efficiency the individual ceases to be a factor of first importance. The process of development, whether considered in its economic, political or purely professional relations, demands the subordination of the interests of the individual to the larger interest of the organic whole. The dominant and controlling feature underlying an infinite variety and complexity of details of that upward movement of professional and social evolution is compatible with a remarkable simplicity of governing principle. Our plain duty is accordingly to endeavor to understand the nature of that governing principle, which is distinctive and characteristic, in that it does not regard the interest of existing members as supreme, but is seeking to establish conditions which are favorable to the interests of a larger future.

As regards the question of the relation of medical work and progress to our social system, the time is probably ripe for a revision of certain elemental and fundamental principles and customs, although it is obvious that neither social agencies nor the general public manifest a proper comprehension of its necessity. Whilst science is telling us about the pathologic intricacies of disease processes, their bacteriologic causation and cure, with unparalleled rapidity, important social and economic questions that affect especially the comfort and health of our teeming town-bred populations are subordinated. Again, in a land of popular civil government the medical profession should be organized in a manner that would render it equal to enlarged duties which naturally should devolve on it. I refer to such matters as the control and regulation of asylums for the insane, municipal health boards and the municipal hospitals for the sick poor, for contagious diseases and the like.

Certain tendencies of modern American life, considered with reference to the welfare both of the medical profession and general public, offer a most promising field for investigation and progress. The temptations of the practical, over-strenuous life of the present and past generations have left their impress on our profession. Something, however, must be ascribed to our nervous climate, reinforced by certain elements of the American spirit-aggressiveness and an unconcealed idealism. Neither should the power of the initiative of the American, his shrewdness and his energy be overlooked. It may be doubted, however, whether there have been accomplished achievements and results commensurate with the impetuosity that characterizes all paths of professional activity. The universal spirit of haste has taken possession of our professional life; it permeates the air of the age, and the principal cause of this state of affairs is to be found in our ardent, everyday ways of living, and its cure must result from a readjustment of the home life and habits of the professional and other classes. It means a return from our present-day restlessness and rush to a quieter period, to a "Mansfield Park," with its charm of quiet village life; a return to a normal life, with natural intellectual tastes, and to calm, patient, original observation that fosters vital force and successful endeavor.

If authors and investigators were to bring forward only definitive and well-weighed pronouncements on all points at issue, it would carry us from the surface to the heart of things, and our labors would be more strongly marked by originality and power.

The spirit of undue haste which characterizes our national life is nowhere better exemplified than in American medical literature, despite its many virtues, its broad, liberal spirit and freshness. Never, in American history, whether deliberately or unconsciously, has so much current literature been placed at the disposal of physicians. Too generally medical thought and opinion, which is not of necessity medical truth, finds literary expression. The obvious weakness of it all is an enforced tendency to waste one's time in reading matter which is unapproved by common opinion. Extending this thought, it may be questioned whether to carry

views and ideas beyond the domain of existing knowledge does not hinder rather than facilitate progress.

There is a list of honor among American writers, and it embraces authors whose literary product shows not only a sharp scrutiny of facts, but also the highest and most characteristic utterances in medicine. Indeed, the worth and power of American medical literature, either in its content or method, scarcely receives an unprejudiced estimate abroad.

In the field of letters we point with inordinate pride to the late Dr. Oliver Wendell Holmes, and our contemporary, Dr. S. Weir Mitchell. Fiction by medical authors lives and will live in America.

It may be questioned whether American nationalism, as evidenced by the creation of a native literature, should be the principal aim, although the consistent use of American material is to be advised and encouraged. We need to retain the conservative European spirit and keep wide ajar the door that leads to the treasures of Continental literary traditions. Foreign peoples are and have been immigrating by the hundreds of thousands yearly; they have penetrated into the remotest points of this country, carrying effective training with them in many instances. Hence, admitting that the pre-science of genius is the possession of many, there are fewer distinctly American medical authors than at first blush would appear.

"The Celt is in his heart and hand.
The Gaul is in his brain and nerve;
Where, cosmopolitanly planned,
He guards the Redskin's dry reserve."

Acknowledgment is due the great value and significance of the unparalleled heritage handed down by the older nations, particularly England, Germany and France. The path of fame for a nation no less than for an individual lies in the direction of constructive effort and sensitive receptiveness of the impressions and tendencies of the age, irrespective of territorial limitations, and of a keen sympathy and close touch with the movements of the times in all lands.

Our literature is not an indigenous growth, yet stern of purpose; it is not, and, let us hope, never will be, sluggish in turning to foreign sources. It has, however, developed certain characteristic features, a distinct national flavor and a perfume "as plainly native as the arbutus."

American industry, with its attendant wealth and power, and the enlarged opportunities it offers to all classes of society for successful business enterprise, has quite generally proven attractive to, and often filled with fervent hope, the American physician, and with increasing means he has found his social position to improve.

In America the achievement of considerable financial success, however, is possible without taking high ground in a professional or ideal sense. The medical profession is integral in the effects of our economic evolution; it obtains stray glimpses of the avenue of glittering gold; but its central effort, if it desires to remain true to human perspective, contemplates a systematic development of its pecuniary, mental, moral and social powers.

The tendency to gregariousness in American cities is in no specific direction more evident than

in the medical profession; hence success is and will continue to be an increasing difficult problem, a circumstance to be reckoned with, no matter what our meaning and ideals as a national profession. This portends in its last analysis the necessity of better training and equipment for everyday duties of the practitioner.

America stands in need of further reform in medical education and the immediate establishment of one authority—one licensing body; and self-created schools must place themselves in a position in which they can worthily assist in the execution of a scheme of higher national medical education. Professional ascendancy in future will demand the creation of a homogenous and adequate standard of qualification for entrance into medical schools.

The relation of social conditions to disease is a topic that is becoming more and more insistent with the reflections that are the natural accompaniment of advancing knowledge.

A backward look reveals an embryo nation steeped in an arduous task—the subjugation of a continent, at the expense of unceasing physical toil. This necessitated an open-air existence, which resulted in a vigorous, hardy race. Then followed the integration of frontier villages, of larger and smaller towns, and life meanwhile became brighter and more piquant. For long generations the abandonment of rural life, the changed habits of living, the enforced pursuit of new and less healthful callings, too often from motives of personal comfort and even social expediency, and the universal tendency to overcrowding in town populations, resulted in a modification of the character and incidence of all leading diseases. It goes without saying that respecting the effects of our social conditions and climate on disease, the particular standpoint of our fathers was radically different from that of their children. Floyd M. Crandall has recently directed forcible attention to the fact “that never have such radical changes been witnessed in the habits of life and in human diseases as those in this country during the last half century.”

Fortunately, agencies are at work looking to the socialization of the American agriculturalist and the amelioration of the ills due to overcrowding in large municipalities. This is a movement which in the entirety of its scope embraces numerous potent forces whose federation promises to effect in time rural social regeneration. An organized effort has in several states been already initiated, and in the conferences held and in contemplation, looking to the betterment of rural life, the co-operation of the medical profession is invited. Modern agencies, as improved highways, the introduction of the telephone, trolley lines, rural mail delivery, are socializers no less than economic facilities. In addition to these physical influences, marked improvement also comes from increased educational opportunities, farm organization and the various functions of the church.

These socializing influences and forces tend to counteract the current of bygone days from the farm to the city; they likewise bid fair to become a factor of first importance in minimizing, if not actually counteracting, in due season, the ill effects of over-dense urban populations. It may, however, be remarked that the impoverished classes, espe-

cially the great immigrant contingent, will be far less likely to return to a rural environment than the well-to-do, and yet it will shortly affect the social and economic conditions as well as the vital statistics of the wage-earning classes. We may confidently expect a greater physical efficiency, a higher bodily standard, though municipal sanitation will be always required, and remain the principal factor in strengthening the powers of resistance to hostile environment. One point of common agreement is that as a result of the rapid advances in sanitation and improved methods of treatment, there has been a notable decrease in prevalence and fatality of most infective diseases, particularly those more or less fostered by overcrowding (for example, phthisis, diphtheria, diarrheal diseases, etc.). Three well-defined classes, however, have, according to the census for the decade ending May 30, 1900, distinctly increased; they are cancer, affections of the kidneys and the degenerations, fatty and fibroid. Thus during an increase in the population of 50% in the United States, myocardial degenerations have increased 150%, and certain types of chronic nephritis have also risen in frequency to nearly 200%. The determination of the causes of this rapidly increasing frequency of these morbid states is clearly the task of the medical profession.

Respecting the degenerations—myocarditis, arteriosclerotic changes and kidney diseases—Crandall says: “The power of alcohol in the form of malt liquors to produce degenerate changes is so well known to pathologists that the conclusion is irresistible that the radical increase in these diseases comes largely from changed drinking habits.”

The notable increase in these morbid conditions, however, is not due to a single cause, and substantial progress cannot result from too much emphasis on any one agency whose undoubted potency remains undemonstrated.

It is probable that a more universal application of refined methods of diagnosis accounts in a measure at least for the apparent disparity in the number of cases of nephritis and myocardial degeneration in recent times as compared with the showing of older statistics.

The census between 1890 and 1900 indicates an increasing prevalence of two additional diseases, in respect to both of which progress in our knowledge has been slow and never encouraging. I refer to diabetes mellitus and lobar pneumonia. The census previously referred to indicates that chronic diabetes mellitus has nearly doubled in point of frequency in a single decade.

Whilst we shall continue to look to the bacteriologic laboratory for the discovery of the definitive cause of this metabolic ailment, and to the pathologist for a mind's-eye picture of the morbid state of the tissues, the data obtainable from an investigation of the manner and habits of life, which exert more or less etiologic influence, are of intrinsic medical importance and would serve as accessory factors in diagnosis as well as straws for the application of measures for treatment.

Although impossible to recognize a boundary line between the “variables of health” and disease in chronic diabetes mellitus, it cannot be doubted that abnormalities of the glycolytic functions of the liver and pancreas, associated with inappreciable

structural changes (more especially in the cells forming the islands of Langerhans) which interfere with proteid metabolism and the metabolic disturbances, are dependent in large measure on the over-use of the mind, intemperance and irregular habits of body; in a word, on improper modes of living.

Physiology has contributed much to the intricate processes involved in the nutritional diseases. Morbid physiology (general pathology) is most intimately bound up with the modes and predilections of American life, particularly of the so-called privileged classes.

Diseases and conditions that are successfully treated by a correction of the mode of life are apt to be regarded as functional in nature, when, in reality, definite although undiscoverable structural lesions already exist, the foundation of an insidious and progressive disease already laid.

Now it is conceivable that a broader application of data as yielded by vital statistics would render more clearly recognizable the terrible significance of an enlightened public, living in idle equiescence to positively injurious prevailing customs. A federation of forces, however, in connection with the investigation of special diseases even, is necessary to make this branch of inquiry productive of really important information; for example, the co-operation of committees on vital statistics with the creation of centers under the auspices of a national organization, such as the American Medical Association, would prove effective. I would instance lobar pneumonia, which, as before stated, is increasing in prevalence, as a disease in which the light of future investigation after this method of research would prove preliminary to important discoveries and decisions. Indeed, the local diversity in social conditions and climate in different sections which are far separated by geographical distances in this country renders such a procedure an absolute necessity. The statistical data gathered by individuals, notably those of E. C. Wells, are of real value, and one point approximately settled is that the death-rate by decades during eighty years is practically unaltered — "certainly not decreasing." The census for the decade between 1890 and 1900 shows an increased prevalence of this disease from 186 to 191 per 100,000.

A marked numerical increase in the number of cases of pneumonia has taken place since the advent of epidemic influenza,¹ but this does not account for the slowly rising incidence of the disease during previous non-epidemic seasons. Other reasons have been given for the augmenting prevalence of pneumonia: increased facilities for travel and the tendency for people to congregate (Wells), the highly infectious character of the disease and the neglect of prophylactic measures in crowded centers (Walsh). Among accessory causes of the increased prevalence of pneumonia may be mentioned change in the prevailing meteorologic conditions. As shown elsewhere, the wanton destruction of the native forests has been attended with an exaggeration of the range of variability of such meteorologic conditions as temperature and humidity. It has been long known and universally recognized that this disease bears a vital relation to the seasons, and that at the greatest morbidity coincides with the most

pronounced climatic changes. It is probable that the increased incidence of the disease will be shown to be dependent in part on augmenting prevalence of visceral degenerations, particularly of the cardio-vascular system and the kidneys. Be it remembered that in a large measure these are the direct or indirect result of an era characterized by undue devotion to business, social excesses and club life, with its attendant unseemly hours and unconcealed conviviality. It must be confessed that the extent to which lobar pneumonia is dependent on these degenerations acting as predisposing factors is imperfectly known, but it cannot be doubted that a conservative attitude toward the question accords to them a prominent position among the agencies unfavorably affecting the prognosis, as shown by a table.

This table † comprises all necropsied cases of lobar pneumonia at the Philadelphia Hospital for a period of six years, from Jan. 1, 1896, to March 1, 1903.² Out of a total of 275 cases, 250, or about 90.9%, showed cardio-vascular lesions, principally chronic endocarditis and general atheroma of the vessels. A small number of the cases, 14, or 5%, showed acute plastic pericarditis, and 11, or 4%, chronic pericarditis. Renal lesions were recognized in 90.5% of the totality of cases. Chronic interstitial nephritis was noted in 145, or 52.7%; chronic parenchymatous nephritis in 50, or 18%; and acute nephritis in 38, or 13.8%. Among the remaining 25 cases was one of renal calculus, another of renal tuberculosis, and in many of the remainder subacute nephritis was noted.

These figures afford strong presumptive evidence that renal and cardio-vascular degeneration rank as potent predisposing conditions, and clear and convincing proof that they bear a close and vital relation to the high mortality rate of lobar pneumonia. It should be stated that the patients admitted into the Philadelphia Hospital belong to the pauper element of society, and the subjects are principally adults.

The reports of the health departments of leading cities, in particular that of New York, furnish valuable data from which important tentative influences may be drawn, but sure ground can result only from research work of a broader character than has yet been undertaken in this country. From the record of vital statistics of Philadelphia and New York I have compiled two tables, § which show that pneumonia is more or less limited to centers, and these correspond in the main to the most densely populated areas, with their allied conditions of squalor and poverty.

Pneumonia, like other acute infections that prevail epidemically, shows a wavelike character, on comparing different years for the same locality. Exclusive of epidemic outbreaks, there is an evident tendency to a preponderating incidence in overcrowded districts and among the impoverished classes. Thus the average mortality rate for four years in New York, taking the eight wards which are most densely populated, from the tabular list is 18%.

The fourth, sixth, seventh, tenth, eleventh, thirteenth, fourteenth and seventeenth wards of New

† Table No. 1, which is omitted.
§ Nos. 2 and 3 omitted.

York City were embraced in this estimation. In contrast with the figures just given, eight wards representing the most sparsely settled portions of the city of New York (for example, first, fifth, eighth, ninth, fifteenth, sixteenth, eighteenth and nineteenth) gave for the same period of four years an average mortality of 14.3%.³ It was observed in the compilation of these mortality statistics that an elimination of the epidemic periods would make the differences in percentage dependent on the population somewhat greater.

In arranging the statistics for Philadelphia I have included only those wards in which the inhabitants were equally distributed throughout the entire ward. *Per contra*, wards having a large area and a low population per acre, but this population located in certain sections of the ward only, have not been included. Thus the following wards became available for the purpose of contrasting those giving the highest with others showing the lowest mortality: First, second, third, fourth, fifth, sixth, seventh, ninth, tenth, eleventh, twelfth, thirteenth, fourteenth, fifteenth, sixteenth, seventeenth, eighteenth, nineteenth, twentieth, twenty-eighth, twenty-ninth, thirtieth, thirty-first, thirty-second and thirty-seventh.⁴ The eighth ward was not included on account of being inhabited principally by a better-to-do class, and on account of containing the Pennsylvania Hospital, the former condition lessening the liability of pneumonia, while the latter institution named would tend to increase the mortality from this disease, since many of its patients come from the third, fourth, fifth and sixth wards.

The portion of the city west of the Schuylkill River was excluded from this computation for reasons similar to those just mentioned.

Out of the twenty-five wards included in our figures I have estimated a percentage of deaths from those showing the most dense population per acre, allowing for the location of hospitals, homes, etc. (for example, second, third, fourth, seventh, thirteenth, seventeenth and nineteenth wards), and I find the percentage of deaths from pneumonia to be 12.8%. Those wards showing less dense population, the first, ninth, tenth, sixteenth, twenty-eighth and thirty-second, gave an average of 9.5%.

The second, third and fourth wards were occupied largely by foreigners (Italians, Russians), and showed the highest percentage of deaths from pneumonia, while the seventh ward, which contains a large colored population, also shows a very high death-rate.⁵

As shown by MacDongall's statistics, unfavorable occupational conditions probably have less effect in causing pneumonia than phthisis. In my own investigations it was observed that divisions of Philadelphia having an industrial population, modestly though comfortably housed, furnished a death-rate but little in excess of that of the sections inhabited by the well-to-do. The whole subject of occupational diseases, eminently important to the medical world, is closely united with the social and economic conditions of the wage-earning classes, but its consideration here would lead me too far afield.

² For permission to examine and employ the records of this hos-

pital, the writer is indebted to Dr. J. V. Shoemaker, president of the Board of Charities and Corrections.

³ The writer desires to acknowledge, with thanks, the kind aid of Dr. William H. Guilfoxy, Registrar Department of Health, New York, in furnishing data.

⁴ The following wards have not been included in the estimation of the lowest percentage, for the following reasons: The twelfth ward, while it shows a low population per acre (86), has a number of hospitals and homes which contribute largely towards its high death-rate from pneumonia. The second and third wards show a population of eighteen and nineteen per acre; there are but few children under five years and few aged persons living in these wards, and this lessens the mortality from pneumonia. The twenty-first and twenty-second wards, because they are occupied mostly by the well-to-do classes. The fifteenth, while it has been included in my calculation, contains a large colored, Italian and French population.

⁵ My acknowledgments are here due to Dr. L. Napoleon Boston for assistance rendered in connection with the statistics gathered in Philadelphia.

DIFFERENTIAL DIAGNOSIS IN DISEASES OF THE GALL BLADDER AND DUCTS.¹

BY GEORGE EMERSON BREWER, M.D., NEW YORK.

DURING the professional experience of the writer, the surgery of the gall bladder and ducts has passed through three distinct phases: the first, in which little or no attention was paid by surgeons to diseases of these organs, as evidenced by the fact that the entire subject was practically ignored by surgical writers; the second, in which surgeons occasionally operated for the late sequelæ of these conditions, as in empyema of the gall bladder, intra-abdominal abscess, ulcerative or gangrenous cholecystitis, an impacted calculus in the common duct, or intestinal obstruction from the presence of large concretions which had ulcerated through the gall bladder into the alimentary canal; and third, the gall-bladder surgery of the present day, in which surgeons not only seek to relieve the dangerous sequelæ of neglected disease, but by early recognition and timely intervention seek to eradicate the disease at a period when it can be accomplished with relative safety, and thereby avoid the serious septic and cholemic terminal conditions in which operative procedures are attended with great risk and a very considerable mortality.

The same sequence of events has been observed in the development of the surgery of the female pelvic organs, the kidney, the vermiform appendix and the alimentary canal, the progress in each instance being due to a better understanding of the pathology and general behavior of the various diseased conditions, a gradual improvement in operative technique, and the ability to arrive at an accurate diagnosis at an early period. It is the last of these factors in the surgery of the gall bladder and ducts, to which attention will be directed in this communication.

In the early part of the first period, referred to above, but little was accurately known regarding the nature of the various affections of the biliary passages, which gave rise to the clinical symptoms of jaundice, colic, vomiting, pain and tenderness in the right upper quadrant of the abdomen, practically all cases being clinically classified as gastro-duodenitis or catarrhal jaundice, gallstones or cancer, and although isolated cases had from time

¹ Read at the sixth meeting of the Congress of American Physicians and Surgeons, Washington, D.C., May 13, 1903.

time been reported as having received surgical treatment, notably those of Bobbs, Marion Sims and Langenbuch, these affections were generally regarded by the profession as belonging exclusively to the domain of the practitioner of internal medicine.

In the latter part of this period the importance of inflammatory conditions of the gall bladder began to be recognized, and, as in the case of the vermiform appendix, the relationship between these and the localized and spreading forms of peritonitis was appreciated.

The second period began with the publication by Courvoisier of his masterly work on the pathology of diseases of the biliary passages, in which he reports not only his own sixteen cases, and the twenty-seven cases of Kocher, Kappeler, Socin, Krönlein, Fritzche, Kauffmann, Kunz and Niehaus, but gives in addition a complete review of all the literature of the subject, and, by a careful analysis of an exceedingly large collection of clinical reports and autopsy findings, is able to establish certain facts bearing upon the pathology and symptomatology of these conditions which have formed the framework of our present knowledge of the subject.

The facts presented by Courvoisier in this work were early demonstrated to the profession that in the great majority of instances these affections could only be relieved by surgical intervention. The result of this publication, therefore, served to awaken a very general interest among surgeons in all parts of the world, and in the decade which followed many new and ingenious operations were devised and successfully carried out; much was added to our knowledge regarding the pathology and general behavior of these diseases, gained chiefly by accurate observation of the conditions found at the time of operation; and by a careful comparison of these findings with the clinical history observed before operation many facts contributing to a more accurate diagnosis have been established.

Encouraged by the success which attended the surgical treatment of these affections, and which contrasted sharply with the frequent failure of the expectant or purely medical method of treatment, surgeons began to advise and carry out early prophylactic operations, especially in those conditions caused or aggravated by the presence of calculous formation. This advance brought the profession to the third period.

The tendency in these early operations, as in those upon the appendix and kidney, is to greatly reduce the sufferings and dangers which accompany the more advanced stages and sequelae. Obviously these advantages cannot be generally secured until the ability to arrive at an early special diagnosis is required by the profession at large, and when likewise the unreasonable prejudice against early and prophylactic operative procedures is overcome. When these two conditions are realized a fourth and real period in the development of gall bladder and duct surgery will have arrived.

As it is only by a comparison of carefully recorded clinical histories with the findings at operation or autopsy that substantial progress has been made in diagnosis, and as data bearing on this subject are constantly being furnished from reliable sources, it seems desirable from time to time to

review the current literature and to present in concise form the important facts bearing upon this subject. This has been creditably done in the past by Robson, Waring, Kehr and others. Perhaps the most important contribution to the subject, since the work of Courvoisier, is the communication of Prof. Hans Kehr, entitled, "Anleitung zur Erlernung der Diagnostik der einzelnen Formen der Gallenstein-Krankheit," published in 1889, in which the writer presented to the profession a report of his 433 operations on the gall bladder and ducts. In these reports the symptomatology of each case is carefully recorded, as are the actual pathological conditions found at operation or by autopsy, and his work undoubtedly furnished the most important collection of reliable data upon the diagnosis of these diseases which had then appeared.

Stimulated by a perusal of this interesting monograph, and actuated by a desire to present in the form of a simple chart, for the use of students, the essential facts in diagnosis of these conditions, the writer in 1900 undertook a review of reports which had appeared up to that time, giving symptomatology and accurate anatomical findings, together with the statements contained in the treatises of the best acknowledged authorities on the subject, to which was subsequently added the facts gleaned from a comparatively limited personal observation.

This chart, with a brief explanatory paper, was presented by invitation to the surgical section of the Buffalo Academy of Medicine, on Nov. 5, 1900, and has since been used by the writer in his section teaching in the College of Physicians and Surgeons.

Since the publication of that chart a number of important communications on the subject have appeared, notably by Kehr, Richardson, Murphy, Oschner, Mayo, Ferguson, Riedel, Allen, Stockton and others; and although the writer finds no reason to alter the chart in any material respect, for he believes that it still represents an accurate, though perhaps incomplete, statement of the typical symptoms and signs of the various pathological processes,—yet a number of exceptions to the typical clinical types of disease must be described, and the results of the more recent contributions added. This, and a statement of the facts upon which he based his original conclusions regarding the symptomatology, will furnish the subject matter of the present communication.

A glance at the accompanying chart will show that the diseases ordinarily encountered in the gall bladder and ducts may be divided into three main classes: Calculous disease, inflammatory disease and new growths.

Calculous disease of the biliary passages is of frequent occurrence, according to Riedel and Kehr, being found in 10% of all adult autopsies (the writer found it twelve times in one hundred subjects examined in the dissecting-room of the College of Physicians and Surgeons). In perhaps 95% of all cases it gives rise to no symptoms (Kehr). In the remaining 5% it occasions symptoms which vary in intensity and importance from a slight transitory jaundice or discomfort in the right hypochondriac region to a rapidly fatal septic peritonitis.

One or more stones in a healthy gall bladder with patent ducts, produce, as a rule, no symptoms, and under these conditions the only physical signs pres-

ent are those of a tumor of the gall bladder, caused by the number or size of the calculi.

Tumor of the gall bladder, present under the conditions enumerated above, from the large size or number of gall stones, or from an accumulation of fluid, is usually more easily defined than in inflammatory conditions, on account of the absence of a pericystic exudate and of rigidity of the abdominal wall.

The presence of a number of stones in a gall bladder has occasionally been recognized during palpation by a *bruit* which, according to Petit, resembles the rubbing together of nuts in a bag. This observation has also been confirmed by Courvoisier, Ferguson and others.

Occasionally a stone can be distinctly palpated, as in the case reported by Lessdorf, in which he was able to grasp and appreciate the stone through the separated muscles of an umbilical hernia.

The writer has recently observed a case in which one could grasp a distended gall bladder through an abnormally relaxed but otherwise normal abdominal wall and easily appreciate a large number of stones, one of which appeared to be as large as a walnut.

If a calculus is temporarily impacted in the neck of the gall bladder or cystic duct, pain is produced, often with nausea, vomiting and localized tenderness, the latter best appreciated, according to Murphy, by hooking the flexed fingers beneath the right costal border and instructing the patient to take a deep inspiration. The attack of pain often ceases suddenly with the occurrence of vomiting, which, by relaxing the spasm, allows the calculus to fall backward into the bladder. Muscular rigidity and fever are absent unless inflammation is present. This is an exceedingly common manifestation of calculous disease, often unrecognized, and frequently dignosticated gastralgia, intestinal colic or acute indigestion.

If, however, the stone becomes impacted in the cystic duct, or if the duct becomes permanently obstructed in any other manner, as by a new growth or cicatricial contraction, there occurs a gradual increase in the size of the gall bladder by an accumulation of fluid within the cavity. In the absence of infection this fluid is sterile, and consists of a thin mucus secreted by the mucous membrane, which gradually distends the gall bladder, often to an enormous size, giving rise to no discomfort excepting that produced by pressure from the size of the tumor. In this condition of hydrops of the gall bladder, the walls of the viscus become extremely thin, the fluid is at first bile stained, and later becomes cloudy and often opalescent.

A tumor of this character develops slowly, is situated immediately behind the abdominal wall below the free border of the ribs on the right side, and appears continuous with the liver at a point opposite the junction of the ninth rib with its cartilage. It develops downward and somewhat toward the median line; it moves with respiration, and may permit a lateral pendulumlike motion on palpation. It is generally smooth, of even oval contour, and its consistence may be soft, hard, fluctuating or elastic. The shape of the tumor is variable; it may be round, elongated, pearshaped or reniform (Riedel). A change in the size and shape of a gall-bladder tumor is occasionally ob-

served, and is probably due to dislodgment of a previously impacted stone, or to valvelike obstruction in the cystic or common duct. Petit reported a case in which it could be emptied by external pressure. Goldwitz and Von Lucke have reported cases in which the tumor was apparently due to paralysis from over-distention, similar to that so often observed in the urinary bladder. It may be of interest in this connection to note that the gall bladder has occasionally been found near the median line (Kehr) or under the free border of the ribs of the left side, as reported by Raymond and Carl Beck. Congenital absence of the gall bladder has been once observed by the writer, and Courvoisier has referred to a case in which it was apparently absent, but in reality was deeply embedded in the substance of the liver.

The passage of a stone through the cystic duct may give rise to no painful sensation. Lawson Tait, however, expressed the belief that it causes far more pain than when passing through the large common duct, and Kehr has made a similar statement.

Considerable controversy has arisen regarding the pain caused by the passage of a stone through the healthy cystic and common ducts. It was formerly held that the transit of such a stone was practically the sole cause of biliary colic, and Murphy still believes that true colic, as distinguished from steady pain, discomfort and tenderness, is invariably due to a moving foreign body. Kehr and a number of other authorities, however, hold that pain in gall-bladder or duct disease is practically always the expression of an inflammatory process. The fact that 95% of all cases of calculus present no symptoms, and the fact also that the majority of calculus cases that come to operation present, in addition, signs of inflammation, would strengthen this view.

Ferguson reports a series of experiments on this point made with probes, bougies and water pressure on a case of cholecystostomy with biliary fistula, and concludes that pain may be caused by pressure and spasm, as well as by inflammation.

As the condition of the biliary passages under these circumstances can hardly be assumed to be free from infection, his conclusions cannot be accepted as proving absolutely the non-inflammatory origin of biliary colic. It is probable that the presence of a stone or other foreign body in an infected duct produces colic more frequently than either condition alone. Without attempting to settle the exact etiologic factor in the production of pain, practically all observers agree that acute paroxysmal pain in the upper abdomen is the most constant and characteristic symptom of cholelithiasis. Riedel,² in a recent publication, states that of one hundred cases of epigastric colic (*Magenkrampfen*), ninety-seven have gallstones or adhesions of the gall bladder, two may have ulcer or cicatrices of the stomach and one spasm of the pylorus.

The diagnosis of stone in the hepatic duct is often very difficult. Courvoisier reports fifty-two cases with fairly accurate histories: In four there were no symptoms, in twenty-two pain was present, without any regular type, and occasionally accompan-

² Riedel: Pathogenese, Diagnose und Behandlung des Gallensteinleidens, 1903, Jena.

digestive disturbances and vomiting; in sixteen there were enlargement of the liver and tenderness; thirty-five had more or less jaundice (in six it was distinctly absent); in nineteen there was fever of an intermittent type; in fifteen there was in addition a suppurative cholangitis.

The diagnosis of stone in the common duct is less obscure; the three most important symptoms are jaundice, pain and fever. Practically all observers regard jaundice as the most constant and reliable symptom of obstruction of the common duct. When this symptom is due to calculus, the diagnosis is comparatively easy; when due to other forms of obstruction it is often extremely obscure. Acute temporary common-duct obstruction from stone produces a rapidly developing jaundice, which rapidly subsides when the stone passes into the duodenum. When the stone becomes impacted in the region of the papilla, the jaundice is progressive and often becomes extreme. If, however, the dilatation of the duct above the obstruction, from an accumulation of bile, causes the stone to become dislodged, and it floats upward in the dilated common, cystic or hepatic ducts, the obstruction is temporarily removed, the bile again flows into the intestine, and the jaundice disappears, only to recur when the ducts contract around the stone or it is again impacted at the papilla.

In one of his later publications Kehr³ states that jaundice is absent in 33% of his cases of stone in the hepatic and common ducts, due largely to the absence of infection. He believes that here, as in other portions of the biliary tract, stones may remain latent for long periods of time, giving rise to symptoms only when an inflammatory complication is added. Murphy,⁴ on the other hand, states that, while jaundice may be remittent, it is never completely absent in stone in the hepatic and common ducts. It is difficult to reconcile these divergent statements, emanating as they do from equally accurate observers.

Pain in common-duct obstruction strongly points to stone. In eighty cases of calculus in the common duct reported by Courvoisier, pain was a prominent symptom in fifty-one, absent in ten, and unrecorded in nineteen.

In seventy-nine obstructions from other causes it was present in only nine instances.

In intermittent obstruction from a floating stone, it is generally more acute during the period of obstruction. It is then often paroxysmal in character, radiates to the back and shoulder; rarely is it constant and fixed in one locality. Tenderness is generally more marked nearer the median line, and slightly lower than when the gall bladder is the seat of trouble.

Fever is less constantly present, but when present is generally of a characteristic type. It was noted in nineteen of Courvoisier's cases, while in seventy-four obstructions from other causes it was present but seven times. It is often intermittent in character, and is accompanied by chills and profuse sweats. This type of fever was described by Charcot as *fièvre intermittente hépatique*, and its similarity to malaria pointed out by many other observers. When present with jaundice and colic, it is almost

pathognomonic of stone in the common duct. Although believed by many to be reflex or due to the absorption of bile, most modern observers agree with Schuppel in regarding it as of septic origin, as the presence in these cases of a certain degree of cholangitis is practically constant.

When the flow of bile into the intestine is hindered, the urine will be dark from the presence of pigment; when completely obstructed, the stools will be clay colored.

Tumor of the gall bladder is generally absent. It has, however, been occasionally observed. Enlargement of the liver is frequent and due to the dilated intra-hepatic ducts or to an extension upward of the cholangitis, in which case there will be tenderness over the liver and enlargement of the spleen. Ascites is present only when the obstructing stone is large and presses on the portal vein.

Inflammation of the gall bladder or ducts is present in the vast majority of patients who apply to the surgeon for relief.

Infection of these organs arises generally from an upward extension from the intestine, from an abnormal patency of the duodenal orifice; occasionally from some general septic disease; very rarely from trauma. Thus Courvoisier in fifty-five cases of empyema of the gall bladder found cholelithiasis in forty-one; in two it was thought to be due to trauma, in two to general sepsis, in one to typhoid fever. Inflammation of these organs may be conveniently divided into two general classes—the mild and the severe infections; the former due to the colon or typhoid bacillus, the latter to the streptococcus or some other equally virulent organism. In the great majority of instances cholelithiasis has preceded the inflammation and prepared the way for it.

The symptoms of cholecystitis are pain, localized tenderness, fever and occasionally the presence of a tumor of the gall bladder.

In a mild infection of the organ with the ducts open, insuring free drainage into the bowel, these symptoms may be wanting. If the cystic duct becomes obstructed from stone or swelling of the mucous membrane or pressure from an inflamed lymph node, colicky pains occur, which may radiate to the back and shoulder; vomiting is generally present during the period of obstruction; there are usually also slight fever and general malaise, which disappear with the pain when the obstruction is relieved. Unless the gall bladder be small or deeply seated under the right lobe of the liver, a sensitive tumor may be felt during the continuance of the obstruction. These symptoms frequently subside spontaneously, but the tendency to recurrence is marked.

If chronic obstruction of the cystic duct occurs, empyema of the gall bladder results, giving rise to symptoms of varying severity, according to the virulence of the infecting agent and the resistance of the individual. This condition may also exist with open ducts, as evidenced by Courvoisier's statistics, in which he reports the ducts free in eleven of forty-one recorded cases of empyema. The pain and fever may be wanting, the only symptoms being the presence of a tender tumor in the region of the gall bladder, or, in cases of a small or contracted gall bladder, only a local tenderness or

³ Ein Rückblick auf 720 Gallenstein Laparotomien unter besonderer Berücksichtigung von 90 Hepaticusdrainagen.
⁴ The Diagnosis of Gall Stones, Med. News, May 2, 1903.

muscular rigidity. In the severer cases the pain is acute, paroxysmal and radiating, the fever is high and accompanied by chills and vomiting. A local peritonitis may be present and give rise to intra-abdominal abscess, a condition often resembling appendicitis. Murphy has recently called attention to a rare form of infective cholecystitis, with or without the presence of calculus, in which the symptoms are only those of a severe intermittent fever with chills and great prostration. There is no pain and no jaundice, only a slight tenderness over the gall bladder region. These cases on operation may present only a mild edema of the gall-bladder wall; the bile presents no gross changes. The cases are completely relieved by drainage of the gall bladder.

In the more virulent infections the symptoms often develop with great rapidity, and are accompanied by marked prostration and a rapidly developing sepsis. Perforation of the gall bladder with a fulminating, rapidly fatal, septic, general peritonitis may occur. In a number of such cases reported by Richardson, diagnosis was impossible, the symptoms suggesting only a rapidly spreading peritonitis or an intestinal obstruction without localizing symptoms.

Jaundice is absent in cholecystitis, unless the tumor of the gall bladder or cystic duct or an enlarged lymph node presses upon the common duct.

In inflammation of the common or hepatic ducts, however, jaundice is often present in addition to the pain and fever, but unless accompanied by stone or complete obstruction from other causes is seldom of a severe type. In the more virulent infections of the common and hepatic ducts the process extends rapidly to the intra-hepatic branches and gives rise to general sepsis, often without other symptoms, leading, unless speedily relieved by surgical means, to multiple hepatic abscesses and death. This condition is practically always accompanied by the presence of foreign bodies in the ducts or gall bladder. In seventy-four cases analyzed by Courvoisier, fifty-seven had calculi, seven ascariides, and three echinococci.

While new growths of neighboring organs not infrequently produce symptoms referable to the gall bladder or ducts by external pressure or direct extension, primary new growths in these organs are comparatively rare.

The gall bladder is most frequently affected, and in the great majority of instances the tumor is carcinoma. Sarcoma and adenoma have been reported; the latter, according to Zenker, may undergo carcinomatous degeneration.

Carcinoma was observed, according to Courvoisier, in seven of two thousand five hundred and twenty autopsies. A study of Musser's report, however, published in 1889, gives one the impression that the disease is somewhat more frequent. Three fourths of the cases were in women, the decade furnishing the greatest number being between fifty and sixty. In one hundred cases analyzed by the author, pain was present in sixty-two. It was usually observed in the right upper quadrant of the abdomen, but was often referred to the shoulder, back or epigastric region. In a number of instances it was paroxysmal, and presented the ordinary characters of biliary colic. Vomiting was present in

thirty-nine cases, a palpable tumor in sixty-eight. Jaundice was recorded in sixty-nine patients, ascites in eighteen. Kehr states that the last two symptoms are always due to involvement of the neighboring lymph nodes, causing pressure on the duct or portal vein. The temperature was generally normal or subnormal, fever being reported in but eighteen cases.

As sixty-nine of these cases had calculi, and as absence of calculi was noted only in three instances, it is probable that many of these symptoms were due to the calculi or to an associated cholecystitis or cholangitis.

The only reliable sign which can be detected early is the presence of a hard, irregular tumor of the gall bladder. The diagnosis is exceedingly difficult; in only four of Courvoisier's one hundred cases was the nature of the disease determined during life. The disease is rapidly fatal; in fifty-three cases followed to the end, death occurred in all within nine months from the first characteristic symptom.

Both benign and malignant tumors occur in the bile ducts. Of the benign growths adenomata and papillomata have been reported by Robson; the latter, he states, occasionally undergo carcinomatous changes. Carcinoma of the bile ducts is generally of the columnar cell variety. It occurs with equal frequency in males and females. It is less often associated with calculi than malignant disease of the gall bladder. Of thirty-four cases collected by Musser and Rolleston, gallstones were present in one half the cases only. Of Musser's eighteen cases, fourteen occurred in the common duct, three at the duodenal orifice, three in the hepatic and one in the cystic. The gall bladder was distended in eight, atrophied in one. Stones were present in seven, and suppuration in two. Pain was a prominent symptom in twelve cases; it was frequently paroxysmal, and was often referred to the epigastrium. Vomiting occurred in nine instances, or one half the cases. A palpable but small tumor was observed in eight cases.

Growths occurring in the cystic duct give rise at first to a distention of the gall bladder; those in the hepatic and common ducts to jaundice, and at a later period to distention of the gall bladder and enlargement of the liver. The jaundice is progressive, and in five cases reported by Delafield was the first symptom. Septic cholangitis may develop especially in growths at or near the ampulla of Vater, and give rise to *fièvre intermittente hépatique*. Intermittent jaundice has rarely been observed in such cases, probably due, as suggested by Harri-mann, to sloughing of a part of the obstructing mass, allowing a temporary flow of bile into the intestine; or, as reported by Courvoisier, a pedunculated tumor near the papilla may act as a valve and occasionally permit the passage of bile.

Chronic obstruction of the bile ducts from outside pressure is of frequent occurrence, the causes of this condition in the order of their frequency being carcinoma of the head of the pancreas; chronic interstitial pancreatitis (a condition of sclerosis of the pancreatic tissue frequently limited to the head of the gland—generally due to an infection carried to the gland by the canal of Wirsung, and often associated with inflammatory conditions of the biliary passages); tumors of the pylorus or duodenum;

cysts of the pancreas; enlarged lymph nodes and cicatricial contractions. As would be expected, such pressure, when limited to the cystic duct, gives rise to a gall-bladder tumor (hydrops); when it involves the hepatic and common ducts it gives rise to a progressively increasing jaundice, without pain or fever, distention of the gall bladder, enlargement of the liver and, later, ascites.

In conclusion the writer feels that he cannot do better than to quote with some slight modifications the last few paragraphs from his previous paper regarding the significance of the three chief symptoms occurring in diseases of the gall bladder and ducts.

Pain.—The occurrence of repeated attacks of acute paroxysmal pain, in the upper right quadrant of the abdomen, strongly suggests a lesion of the biliary passages. This suggestion is accentuated if the attacks occur at night, or during fasting, and are accompanied by vomiting and fever. If the pain radiates upward to the back and shoulder, and if an area of tenderness exists under the free border of the ribs, the diagnosis is still more probable.

If in addition to the pain we have a palpable tender tumor under the lower border of the ninth rib, or if there exists a point of tenderness in the same location, with moderate spasm of the upper half of the rectus muscle, in all probability the case is one of cholecystitis. If, on the other hand, there is jaundice but no gall-bladder tumor, we probably have to do with stone in the common duct.

Other conditions giving rise to acute pain in the upper abdomen, to be excluded, are, first, gastric ulcer, in which the pain and tenderness are more generally located in the epigastric or left hypochondriac region, and in which fever, as a rule, is not present; appendicitis, in which vomiting and fever may also be present, but the pain and tenderness are usually located in the right lower quadrant of the abdomen; renal colic, in which the pain originates in the flank and extends downward along the ureter to the testicle, which may be retracted, and which is often accompanied by vesical irritation and hematuria; Dietel's crises in cases of movable kidney, which are generally promptly relieved by assuming the recumbent posture or replacing the dislocated organ; the gastric crises of tabes, in which fever is absent, and although the vomiting is present, there is no characteristic point of tenderness. These cases also show an absence of the patella reflex, the presence of pupillary symptoms, sensory disturbance and ataxia in the extremities. Occasionally, pain in this region, strongly simulating biliary colic, will be caused by the presence of inflammatory adhesions in the region of the pylorus and duodenum, causing a narrowing of the canal with dilatation of the stomach. Aneurism of the hepatic artery (Riedel), interparietal hernia, pancreatitis, intestinal obstruction, or the early pain of a local peritonitis from other causes, has given rise to difficulties in diagnosis; and, lastly, syphilitic hepatitis may present pain and other symptoms almost identical with those generally found in calculous disease of the biliary passages.

Tumor.—A tumor in the right hypochondriac region, which develops slowly and is preceded by a history of cholelithiasis; which is round, oblong

or pear-shaped, with a smooth, convex surface, elastic or fluctuating; which lies immediately under the abdominal wall below the ribs and near the outer margin of the right rectus muscle; which moves with respiration; which allows a certain amount of lateral, pendulumlike motion on account of its attachment above; which cannot be made to disappear like a movable kidney under the ribs, and which is not accompanied by pain and fever, is in all probability a gall bladder distended with mucus (hydrops). If with such a tumor there is a progressive jaundice, it is probably a gall bladder distended with bile from a non-calculous common-duct obstruction. If such a tumor is sensitive to the touch and is accompanied by fever, it is doubtless a gall bladder distended with pus (empyema). If the tumor is ill defined, on account of muscular rigidity, if there are acute radiating pain and marked tenderness in the right hypochondriac region, with fever and leucocytosis, we have generally to do with a cholecystitis with local peritonitis. The presence of a tumor corresponding to the above description, without pain, fever or jaundice at first, but presenting a hard, irregular surface, is in all probability cancer.

Jaundice.—The occurrence of a mild, transitory jaundice, unaccompanied by other symptoms, suggests a catarrhal obstruction of the common duct (a mild duodenitis from indigestion). The occurrence of a temporary jaundice with colic suggests the passage of a stone through the common duct into the intestine. The occurrence of intermittent jaundice, intermittent colic and intermittent fever suggests a floating stone in the common duct. The occurrence of continued jaundice, with chills, fever, hepatic enlargement and tenderness, hypertrophy of the spleen and general sepsis, suggests an infective cholangitis. The occurrence of a progressively increasing jaundice and enlargement of the liver, with a previous history of colic, but without distention of the gall bladder, suggests an impacted stone near the papilla. The occurrence of a progressively increasing jaundice, without pain or fever, but with a tumor of the gall bladder, suggests common-duct obstruction from new growth.

It is also well in this connection to remember the following facts, gleaned from the writings of those most experienced in the surgery of the biliary passages: Gallstones are rarely found in young subjects; according to Sehroeder, only 2.4% occur in individuals under twenty years of age. The same author states that 20% of all female, 4.4% of all male autopsies show the presence of calculi in the gall bladder. Ninety per cent of the women have borne children. Gallstones have been known to escape from the biliary passages into the alimentary canal by ulcerative processes, and to produce intestinal obstruction without giving rise to pain or any other symptom until the evidences of bowel obstruction appear.

In common duct stone the calculus is found in 67% of the cases in the duodenal extremity, in 15% in the hepatic extremity, and in 18% in the middle portion of the duct (Robson).

One half of all cases of common duct obstruction only are due to stone (Robson).

In 70% of the cases of obstruction located in the neck of the gall bladder the pain is referred to

DIAGNOSIS CHART IN DISEASES OF THE GALL BLADDER AND DUCTS.

| Pathological condition. | Pain. | Fever. | Vomiting. | Jaundice. | Tumor of gall bladder. | Urine. | Stools. | Liver. | Spleen. | Ascites. | Remarks. |
|--|---|--|-----------------------------------|--|--|--|--|--------------------------------|-------------------------------------|----------------------|--|
| (a) Stone in healthy gall bladder, ducts free. | No | No | No | No | May be present from large number or size of stones. | Negative | Normal | Not enlarged. | Not enlarged. | No | Generally discovered by accident; often recognized. |
| (b) Stone in healthy gall bladder, cystic duct temporarily obstructed. | May be absent; generally present during obstruction; paroxysmal. | No | May be present when colic occurs. | No | May be present from distention. | Negative | Normal | Not enlarged. | Not enlarged. | No | All symptoms promptly relieved as soon as obstruction is removed. |
| (c) Stone impacted in cystic duct. | No | No | No | No | Present; may attain large size. | Negative | Normal | Not enlarged. | Not enlarged. | No | Hydrops of gall bladder; often unrecognized. |
| (d) Stone in hepatic duct. | Frequently present; irregular type. | Occasionally present. | May be present during pain. | Frequent | No | Contains bile pigment at colored times. | May be clay colored if obstruction occurs. | Frequently enlarged. | Not enlarged. | No | Diagnosis extremely difficult; symptoms ally due to coexisting cholangitis. |
| (e) Stone in common duct; acute obstruction. | Present; acute paroxysmal radiating to back. | Generally present. | Present | Present | No | Contains bile pigment. | Clay colored. | Not enlarged. | Not enlarged. | No | Symptoms rapidly disappear when stone papilla. |
| (f) Stone in common duct; movable; chronic. | Periodic attacks of acute radiating pain. | Present with chills and sweats. | Present | Present; intermittent. | Rarely present. | Contains bile pigment. | Clay colored. | May be enlarged during attack. | May be enlarged. | No | " <i>Fièvre intermittente hépatique</i> " of Charcote; resembles malaria; all symptoms disappearing interval. |
| (g) Stone in common duct; impacted; chronic. | May be absent; frequently present early; may be intermittent; variable. | May be present; variable. | Often present. | Present; progressively; may vary in intensity. | Rarely present. | Contains bile pigment. | Clay colored. | Enlarged. | May be enlarged. | No | Condition may remain for many years only be jaundice with digestive disturbance and loss of weight; history of previous attacks (?). Ascites may be present from pressure of large stone or possibly from hydrops. |
| (h) Cholecystitis sub-acute. | Present; paroxysmal during periods of cystic duct closure from stone or swollen mucous membrane. | Present during attacks of colic. | May be present. | No | Present during attacks of cystic duct obstruction. | Negative | Normal | Not enlarged. | Not enlarged. | No | Tenderness over gall bladder; tendency to curence; generally associated with stone in gall bladder. |
| (i) Cholecystitis acute. | Acute paroxysmal radiating pain; extending to back and shoulder; may be very severe. | Present with chills and sweats. | Present; often severe. | No | Present; tenderness; often muscular rigidity. | May contain albumin and casts. | Normal | Not enlarged. | May be enlarged (sepsis). | No | May follow typhoid or other septic disease; set often sudden; rapid development of symptoms resembling appendicitis; necrosis of walls of gall bladder with perforation, local or general peritonitis. Frequently follows acute cholecystitis; occasionally becomes quiescent, presenting practically no symptoms. |
| (j) Cholecystitis chronic (empyema of gall bladder). | Severe radiating pain at first; may disappear later; tendency to recur. | Present; severe at first; may diminish later. | Present at first. | No | Present; with tenderness; may attain large size. | Negative | Normal | Not enlarged. | Not enlarged. | No | Generally tenderness over gall-bladder and no tumor; local peritonitis; diagnosis extremely difficult. |
| (k) Cholecystitis previously diseased and contracted gall bladder. | Present; often severe; paroxysmal. | Present; often with chills and sweats. | Present | No | No (occasionally present, due to perityphlitic exudate). | Negative | Normal | Not enlarged. | May be enlarged (sepsis). | No | Often follows severe infections of gall bladder generally associated with stones in common hepatic ducts; severe sepsis; generally in virulent infections (streptococcus). |
| (l) Cholangitis of hepatic and common ducts. | May be absent; generally present when obstruction exists; severe induration; tenderness and pain over liver in intra-hepatic cholangitis. | Present; chills; sweats; severe prostration; general sepsis. | Present | Present; variable. | No | May contain bile pigment, albumin and casts. | May be clay colored. | Enlarged. | May be enlarged (sepsis). | No | Digestive disturbances, progressive loss of weight and asthenia; cachexia; rapidly fatal. |
| (m) Carcinoma of gall bladder. | No; may occur late in disease. | No | No | Present late (portal glands). | Hard, irregular, movable tumor at first, later diffuse induration. | Negative (at first). | May be clay colored, later. | Enlarged late in disease. | May be enlarged (pressure on vein). | Present late. | Very rare; both benign and malignant growths have been reported; diagnosis difficult. |
| (n) Tumor of cystic duct. | No; may occur late | No | No | No | Present when obstruction exists. | Negative | Normal | Not enlarged. | Not enlarged. | No (?) | Very rare; diagnosis difficult. |
| (o) Tumor of hepatic or common duct. | No; may occur late | No | No | Present; progressive. | May be present from distention with bile. | Contains bile pigment. | Clay colored. | May be enlarged. | Not enlarged. | May be present late. | Malignant tumors most common; chronic atypical pancreatitis from previous infection; biliary passages may remain after caustic disappearance; enlarged portal glands; fatal. |
| (p) Tumor of neighboring viscera obstructing chronic obstruction of common duct. | No; may occur late | No | No | Present; progressively; may be extreme. | Present; generally from distention with bile. | Contains bile pigment. | Clay colored. | Enlarged. | May be enlarged late. | Present late. | |

New Growths.

II.

I.

Calculus Disease.

the right sub-scapular region, in 10% to the left sub-scapular region; and in 20% to the precordia, sternum, right sub-clavicular region or neck (Murphy).

The temperature chart in biliary infection is characterized by angularity rather than by *curves*, and by more or less prolonged periods of complete intermission (Murphy).

Jaundice is absent in from 80 to 90% of all operative cases of gall bladder or duct disease.

Jaundice preceded by colic is practically always due to stone; jaundice without pain is practically always due to inflammation or new growths of the ducts, or to outside pressure.

The bile in all cases of cholelithiasis should be regarded and treated as an infected secretion.

During the presence of a calculous jaundice, the sudden occurrence of acute epigastric pain, muscular rigidity, nausea, vomiting and collapse, without leucocytosis, strongly suggests acute pancreatitis occasioned by the presence of a stone in the diverticulum of Vater (Murphy).

Reports of Societies.

AMERICAN MEDICAL ASSOCIATION.

SECTION ON PRACTICE OF MEDICINE.

W. S. THAYER, M.D., OF BALTIMORE, CHAIRMAN.

FIRST DAY, TUESDAY, MAY 5, 1903.

ADDRESS of Chairman. DR. W. S. THAYER of Baltimore delivered the opening address on

OBSERVATIONS ON THE TEACHING OF CLINICAL MEDICINE.

He compared the curriculum in most of our schools with that which was required in England and France. In Great Britain, for instance, the schools require at least six months' service as a clinical clerk in the medical wards and a similar time as a dresser in the surgical wards of a hospital. In Paris the student was required to give the entire morning to ward work for two years, one year in the medical and one year in the surgical department. He believed that an equal amount of experience should be required in this country, but it seemed to be impossible for the following reasons: (1) The absence of state or national laws requiring such work; (2) the multiplicity of medical schools and the existence of many such institutions unconnected with hospitals of sufficient size to furnish material for the instruction of the students; (3) a widespread prejudice existing in many hospitals against the admission of students to the wards and against the use of patients in general for purposes of instruction. He stated that the problems involved in the study and teaching of clinical medicine differed in no essential from those connected with the teaching and study of physiology, and until we recognized this fact, and met it squarely, our clinics would remain unproductive and our teaching inadequate.

THE BOY'S VENEREAL PERIL.

DR. FERD. C. VALENTINE of New York summed up his advice in the following words: If you want

to be a healthy, strong, successful man, if you want to live a happy life, do not smoke, do not drink alcoholic beverages, do not associate with corrupt people and do not indulge in any vices. If you have been so unfortunate as to lose your health for any of the above reasons, do not take the advice of an advertiser, do not take advertised drugs, but consult your physician.

CONTINUED FEVER, NEITHER MALARIAL NOR TYPHOID: A CLINICAL STUDY.

DR. T. J. HAPPEL of Trenton, Tenn., read this paper. He said that the physicians in the North, as a rule, contended that every continued fever was either typhoid or malarial, whilst in the South many physicians were sure that they had to deal with a third fever, the mortality of which was so slight that opportunities for postmortem study had been so far *nil*. The blood and secretions had been examined microscopically and chemically with negative results. The blood did not respond to the Widal test, and it did not show the presence of the plasmodium malariae. In a former paper he had referred to a number of such cases treated by him in the last ten years, all offering favorable opportunities for careful study at the bedside. He then detailed six additional cases that he had treated since July last, making a total of about one hundred cases. He emphasized the points of difference from a clinical standpoint, and added that the bedside study taught plainly one thing and the work in the laboratory another. These cases were not ushered in abruptly by a chill, but they had usually for a few days prodromes of malaise, then rigors, sometimes by a slight chill, followed by a slight rise in temperature, which did not attain its maximum for from three days to a week. Whilst this fever presented marked remissions, for the first week they were not so decided as in the second week, but were more so in the third week, amounting to intermissions with profuse sweatings. The chills, or cold rigors, were accompanied by aching of sometimes one set of muscles, and sometimes of all, resembling in that respect grippe. After a day or two all pain ceased, and the patient complained of nothing. The intermissions varied from one to four in twenty-four hours, and could be made more marked by sponging with tepid water in all cases, by aconite and gelsemium in a few, and by the coal-tar derivatives in almost all of them. One of the most marked peculiarities of this fever was the disproportion between the pulse rate and the temperature. The ratio was frequently reversed, the pulse beating at the normal to 90, with a temperature of 103 to 105 degrees or even higher. The hand applied to the pulse and then to the forehead would lead one to say that the patient was free from fever, when the thermometer in the axilla or mouth would reveal a high temperature.

SOUTHERN FEVERS.

DR. WILLIAM KRAUSS of Memphis, Tenn., read this paper, and summed up his remarks as follows: (1) A very sudden hyperpyrexia in midsummer was more apt to be sunstroke than "congestion." Don't give quinine without cause. (2) The malarial leucocyte count was only collateral evidence of

malarial infection, and the count must include all the cells in the spread. (3) The Widal test might lead us into error in a small percentage of cases; the blood culture test was more difficult, and had no negative value. (4) A chill or fulminant onset of a typhoid fever was not sufficient evidence of a complicating malaria. (5) A chill or sudden disturbance of a temperature curve during convalescence in typhoid fever was not necessarily malarial. (6) In a malarial infection, the persistence of an irregular sub-continuous fever after thorough cinchonization was not evidence of a typhoid complication or of remaining plasmodia. (7) A positive diagnosis of summer-fall fevers was not always possible. (8) In the hygienic management of summer-fall fevers we should presuppose a double infection, irrespective of symptoms. (9) Some of the summer-fall fevers were typhoid, some were malarial and a few of them were neither one, but the writer was opposed to the belief in an x-fever.

A CLINICAL OBSERVATION OF NINETY CASES OF TYPHOID FEVER WITH FOUR DEATHS, WITH SPECIAL REFERENCE TO THERAPEUTIC FASTING.

DR. R. M. HARBIN of Rome, Ga., read this paper. The conclusions that he adduced were as follows: (1) Fasting and a restricted diet were indicated because of pathologic conditions. (2) A clinical fact maintained that emaciation occurred independently of the amount of food taken. (3) All severe cases should be subjected to fasting for twenty-four to forty-eight hours, to relieve the active symptoms, which exhaust the patient more rapidly than the lack of food. (4) After a fast should be prescribed a restricted diet of broths, diluted milk, etc., in definite quantities. (5) Gelatin prevented too rapid emaciation in certain cases and rendered hemorrhage less liable. (6) The cold bath or the modified cold bath was more effective during a fast. (7) Peristalsis favored the absorption of toxins, and cathartics should be used only to remove undigested food. (8) The presence of intestinal ulcers should be assumed to exist in every case, and the proper treatment was rest, which was better attained by fasting and a restricted diet, thus preventing hemorrhage and perforation. (9) The presence of diarrhea and vomiting indicated the adoption of the fasting treatment. (10) Fasting and a restricted diet shortened the course of the disease, and many cases ran an abortive course after the amphibolic period. (11) Many of the vaunted cures from specific drugs were dietetic in fact. (12) Recrudescences were nearly always due to dietetic errors. (13) In the report presented there were forty-eight cases without a death. Of eighty-seven whites, two, or 2.2% died; of the colored, two died. The low mortality of 4.4% of all cases he ascribed to the therapeutic fasting.

A REPORT OF FIVE HUNDRED AND TWENTY-NINE CASES OF TYPHOID FEVER IN COLORADO.

DR. J. N. HALL and DR. C. E. COOPER of Denver, Colo., presented this paper. From an analysis of a considerable number of cases covering twenty years in different parts of Colorado they concluded that typhoid fever was practically the same disease there as elsewhere. Many of the

cases called mountain fever by some had been included in the series presented; they knew of no such disease as "mountain fever." Typical examples have had hemorrhages, rose spots, Widal reaction and many of the complications of typhoid, and were certainly typhoid. The false name was gradually passing out of use. In 1889 Dr. Hall concluded that, from an analysis of his first one hundred and eight cases, typhoid fever was milder there than in the East; but a wider experience had convinced him that it did not differ materially in this nor any other respect from the disease as reported from this or most other countries. He believed that diarrhea was less frequent in Colorado than elsewhere.

DR. T. B. FUTCHER of Baltimore advocated the frequent examination of the blood serum for the Widal test. This was the routine at the Johns Hopkins Hospital, and every case was submitted to such an examination when he was discharged from the hospital. The possibility of a paratyphoid infection should be borne in mind. With reference to the administration of the coal-tar derivatives, he said we should remember the fact that they frequently gave rise to chills and sweating of a rather severe grade. Chills and sweating in typhoid might occur at the onset, with the advent of complications, and at the time of convalescence and with the giving of the coal-tar derivatives.

DR. JAMES TYSON of Philadelphia said that, during an experience of thirty years, the tendency had been to limit the number of continued fevers. Each winter he ran across several of these anomalous fevers which at first eluded diagnosis, but invariably turned out to be either typhoid fever, malaria or some of the more unusual modifications of typhoid fever, such as paratyphoid or colon bacillus infection. On the other hand, there was no doubt but that a number of these continued fevers were due to irritative causes, such as intestinal indigestion or the so-called ptomaine poisoning, where the irritation would be kept up for a certain length of time.

DR. J. A. WITHERSPOON of Nashville, Tenn., had seen several cases such as described by Dr. Happel, but the disease started suddenly and not gradually; it did not occur at the same season as typhoid; it might occur at any time from the cradle to the grave; one attack made another more liable to occur, and he had seen five attacks occurring in the same individual; the pulse was rather rapid, prostration was early and the sweating marked; there was an irregular type of fever, and this was the most noticeable feature; the fever often resembled the septic type; the abdomen was not tympanitic, but rather flat or scaphoid; constipation was more often present with the passage of hard scybalous masses; there was not a condition of hebitude but rather that of irritability; epistaxis was rare; herpes labialis was common.

SECOND DAY, WEDNESDAY, MAY 6.

WEAKNESS AND DILATATION OF THE HEART DUE TO CHRONIC NUTRITIONAL DISEASES.

DR. G. W. McCASKEY of Fort Wayne, Ind., said that the various causes which acted upon the heart did so in the following ways: (1) A failure

supply sufficient nutritive pabulum to the heart muscles, because of a weakening of the complicated mechanism concerned in this accomplishment; (2) through the chemical influence of retention products which were toxic in excess, and the absorption of foreign substances for the most part in the gastro-intestinal tract; (3) through the partial failure or perversion of the important phenomenon of innervation of the heart muscle; (4) the purely mechanical factor, which was operative from the moment when the cardiac muscle was unable to make an effective ventricular contraction against the resistance offered in the arteries. Slighter grades of dilatation were frequent in chronic gastro-intestinal diseases and in all the severer forms of anemia. The treatment consisted in the removal of the primary disease, improved nutrition, rest, diet, graduated exercise and, in the severer forms, cardiac tonics and saline carbonated baths. In conclusion he emphasized the favorable prognosis of dilatation of the heart in most cases.

MITIGATION OF NONSURGICAL TREATMENT IN INTESTINAL OBSTRUCTION.

DR. JOSEPH RILUS EASTMAN of Indianapolis, Ind., after a brief consideration of the mechanical obstructions, functional closures and the cases that were amenable to treatment by nonsurgical methods, took up briefly the consideration of the difficulties in distinguishing the mechanical from the reflex ileus. He cautioned strongly against the use of morphine, which so masked the symptoms. He claimed that physicians did not promptly diagnose and advise operations in intestinal obstructions, and, as a rule, the surgeon was called in too late. The earlier and better operating lowered very much the mortality. As a rule, the urgency of operation was not so great in obstructions of the large intestines as in closure of the small gut. In the former, sedatives, hot stupes, taxis and enemata might be justly employed for a longer time.

THE OCCURRENCE OF STRONGYLOIDES INTESTINALIS IN THE UNITED STATES.

DR. M. L. PRICE of Baltimore read this paper. He presented an account of one of the rarer nematodes, at least rare in this climate and latitude, though occurring frequently in tropical and sub-tropical countries, the strongyloides intestinalis, a parasite endemic in Cochin China, where it occurred in association with the diarrheas peculiar to that country, and hence called by European physicians Cochin diarrhea."

CLINICAL DIAGNOSIS OF INTESTINAL PARASITES.

DR. CHARLES W. STILES of Washington, D. C., discussed the various methods of distinguishing infection with intestinal parasites, and particular stress was laid upon the diagnosis of hookworm disease.

UNCINARIASIS IN THE UNITED STATES, WITH ESPECIAL REFERENCE TO ITS OCCURRENCE IN TEXAS.

DR. ALLEN J. SMITH, of Galveston, Texas, made a brief statement of known distribution of

the uncinaria in the United States. He detailed eight cases met in the examinations of eighty-eight persons supposedly healthy. He gave the gross and minute features of the parasite, with especial reference to the propriety of Stiles' new species, *Uncinarias Americana*. He also made a comparison with the *Uncinariasis duodenalis* and the *Uncinariasis stenocephala* (dog), and the frequent occurrence of the latter in very similar localities.

TREATMENT OF UNCINARIASIS.

DR. THOMAS A. CLAYTON of Washington, D. C., considered the means which should be adopted to prevent infection with the hookworm, and the destruction of the parasites in those affected. The conclusions he drew from some experimental work done to determine whether or not the alcoholic solution of thymol could be safely used were as follows: (1) The alcoholic solution of thymol was dangerous to dogs even in small doses, chiefly because of its tendency to produce inflammation of the lungs by aspiration. (2) The alcoholic solution even when rendered bland by the addition of oil was dangerous in doses of more than 4 gm. to dogs of 16 or 17 lbs., because of its irritative effect on the gastro-intestinal mucous membrane. (3) In dry powder the drug may be given to dogs in large doses without serious results, no depression, no fall of temperature. (4) Gram doses given hypodermatically cause only local inflammation. (5) There was probably no danger in giving 2 to 4 gm. followed by one to two tablespoonfuls of brandy to a human adult if followed in a few hours by a purgative, such as castor oil or magnesium sulphate. (6) It was probable that the alcoholic solution obtained in this way would be more effective against the parasites, as seemed proven by their much earlier appearance in the stools after the use of the alcoholic solution.

TROPICAL DYSENTERY.

DR. CHARLES F. MASON'S (U. S. A.) plan of treatment, as the result of experience gained in the Southern States, was to give 10 gr. of Epsom salts in half a glassful of water every hour, until a movement was obtained free from blood and mucus. This was combined with irrigation of the lower bowel with warm normal salt solution two or three times a day. So soon as the movements assumed an ordinary diarrheal character, he gave astringents in large doses, such as bismuth subgallate, combined perhaps with a little Dover's powder, every three or four hours. The lower down in the bowel the lesions were seated, the more important became the local treatment by irrigation. In convalescence great care was required in the management of the diet. In the subacute and chronic cases the treatment was somewhat different, but even here salines could be used with advantage in the beginning. The patient should be given an anesthetic, the sphincter well dilated, and the rectum carefully examined with the speculum to detect ulcers, which should be scraped with a curette or touched with pure carbolic acid or lunar caustic. After this the use of saline injections two or three times a day with proper diet often sufficed to effect a cure. Internally large doses of dermatol were useful in such cases.

A CONTRIBUTION TO THE STUDY OF THE SUMMER DIARRHEAS OF INFANCY.

DR. J. H. MASON KNOX of Baltimore, Md., summarized his conclusions as follows: (1) The diarrheal disorders of a large series of children treated in the Thomas Wilson Sanitarium during the summer of 1902 was produced by a bacillus thought to be identical with the bacillus dysenteriae Shiga. (2) The cases in this series presented the clinical and pathological features of the several forms of the summer diarrheas of infancy. (3) There was good reason for the confidence that a proportion, and probably a large one, of the so-called summer diarrheas of infancy were caused by the bacillus dysenteriae Shiga. (4) A confirmation of the work of Duval and Bassett, by establishing the etiology of this yearly epidemic among infants, would make possible the use of more intelligent measures to control and suppress it. (5) More success could be expected from prophylactic measures and from medicinal and serum therapy than ever before.

MALARIAL DYSENTERY.

DR. WILLIAM BRITT BURNS of Memphis, Tenn., discussed the possibility or even probability of there occurring a dysentery with the malarial parasite as a causative factor. He called attention to finding malarial parasites and pigment in the vessels of the intestinal mucosa and to the almost invariable amenability of these dysenteries to quinin therapy.

THE CLINICAL HISTORY AND PATHOLOGY OF AMEBIC DYSENTERY.

DR. H. F. HARRIS of Atlanta, Ga., after considering the macroscopical appearance of the lesions, related the sequence of events that occurred in the puppy after receiving an injection of material containing living amebæ.

A STUDY OF THE CASES OF AMEBIC DYSENTERY OCCURRING AT THE JOHNS HOPKINS HOSPITAL.

DR. T. B. FUTCHER of Baltimore, Md., gave the following summary: (1) In nearly fourteen years 119 cases of amebic infection had been admitted to the Johns Hopkins Hospital. Of these, 118 were cases of amebic dysentery or its complications, the remaining case being one of amebic abscess on the floor of the mouth. (2) Of the 119 cases, 117 were admitted to the medical wards. During this time there were 15,817 medical admissions, the cases of amebic dysentery consisting of 0.73% of the total. (3) Of the 118 cases of amebic dysentery the infection in 82 was apparently contracted in Baltimore and in 13, in the state of Maryland outside Baltimore, or a total of 95 cases contracted within the borders of Maryland. (4) The largest number of cases occurred in the third decade, 35 having developed between twenty-one and thirty years of age. The youngest was a child of two years and eight months and the oldest a man of seventy-one. (5) A point of practical interest was the comparatively large number of infections in children under ten years. Eleven cases, or 9.4%, occurred in the first decade, 6 of these developing in the first hemidecade. (6) The disease was much more prevalent

in males; the series was composed of 107 males and only 11 females. (7) There were 107 whites and 12 blacks, or a proportion of 9 to 1, the ratio of all admissions for all diseases in the two races being 7 to 1. (8) A secondary anemia of moderate grade occurred. A striking feature was the polycythemia in many cases. A moderate leucocytosis existed, that in cases with hepatic abscess being only a trifle higher than that in uncomplicated cases. (9) Hepatic abscess occurred in 24, or 20.3% of the cases. Eight of these ruptured into the lung, producing an hepato-pulmonary abscess. In 15 of these cases that came to autopsy 9 showed a single large abscess in the right lobe and 6 presented multiple abscesses. (10) Perforation of the colon with peritonitis occurred in 3 cases. (11) Intestinal hemorrhage occurred in 3 cases. (12) Five of the cases were complicated by malaria and one by a strongyloides intestinalis infection and two by typhoid fever. (13) The agglutination blood tests indicated that the disease was not associated with dysentery due to bacillus dysenteriae Shiga. (14) A marked feature of the disease was its tendency to relapse, 19 patients being readmitted one or more times. (15) The mortality was high, 29, or 24.5%, terminating fatally. (16) Quinin irrigations afforded the most satisfactory means of treatment.

THE TREATMENT OF ACUTE DYSENTERY.

DR. JOHN M. ANDERS of Philadelphia said that a proper regimen tended to render the course of the disease milder. The patient should have rest in bed, proper ventilation, proper diet, and attention should be paid to the manner of feeding, the aim being to minimize the intestinal contents and thus the amount of decomposable material that reaches the seat of the morbid changes. Properly carried out milk diet made the least intestinal putrefaction. Albumin water was highly serviceable. Ipecacuanha stood pre-eminent among special drugs, but it had no specific action. He advised the use of saline laxatives, particularly magnesium sulphate, which produced an eliminative effect, and depleted the intestinal mucosa and inhibited undue peristalsis. This might be followed with aromatic sulphuric acid or sulphur with benefit. To render the intestinal contents acid, sulphur or sulphuric acid was rational. To meet the pain, irritability and undue peristalsis, opium was indicated. Preparations of bismuth were valuable, particularly in advanced stages, and might be advantageously combined with Dover's powder and antiseptics. He advised intestinal irrigations, but believed they were more suitable and more efficacious in amebic dysentery than in the acute bacillary form. In amebic dysentery warm solutions of quinin were more or less efficacious.

ABDOMINAL PAIN IN PLEURISY AND PNEUMONIA.

DR. JAMES B. HERRICK of Chicago read this paper, and made reference to the pain occasionally seen in the abdomen in pleurisy and pneumonia, which he attempted to explain by the involvement of the lower intercostal nerves and the possible influence of the phrenic nerve. In cases of this abdominal reference to pain, certain abdominal dis-

ases such as appendicitis, cholecystitis, etc., might be simulated. Diagnosis was largely a matter of careful physical examination.

TRAUMATIC PNEUMONIA.

DR. W. T. ENGLISH of Pittsburg, Pa., limited his discussion to concussion and contusion without penetrating wounds or fractures, speaking of the normal and abnormal peculiarities favoring or resisting extrinsic or intrinsic stress, with the citation of cases.

(To be continued.)

Recent Literature.

Diagnosis and Modern Treatment of Pulmonary Consumption. By ARTHUR LATHAM, M.A., M.D. (Oxon.), M.A. (Cantab.). New York: Wm. Wood & Co. 1903.

With the multiplicity of works upon pulmonary consumption one naturally feels a sense almost of satiety in taking up new books treating of this subject, but in the present case one can cordially commend the work not only because it comes from one who holds a distinguished position in this special branch of medicine, but because of its value as a reference book for modern views upon consumption.

In Chapter II he speaks of the importance of hemoptysis as an early symptom of tubercular disease, and devotes several pages to the discussion of methods of diagnosis, special weight being given to tuberculin as a diagnostic agent. The author, evidently, holds this method in high estimation. It is a little difficult, however, to understand the logic of his position when he states that there is no danger from the careful use of tuberculin as a means of diagnosis, and yet condemns as dangerous the use of iodide of potassium to bring out a possible crepitation in an affected area of the lung.

In Chapter V the author concisely speaks of the sources of infection and reinfection, mentioning the differing views upon the transmission of bovine tuberculosis to man, and giving useful suggestions for the destruction of the sources of infection. He believes that foul air as found in ill-ventilated buildings is the most fruitful source of tuberculosis. He fails to allude, however, to soil moisture as a potent factor.

The following chapters are chiefly given up to descriptions of sanatorium and home treatment, the author evidently believing the former to be the most efficacious method of combating consumption in the majority of cases which are not too advanced.

In suggesting methods of treatment he takes a broad ground, and emphasizes the necessity of taking the individual into consideration in every case and of not blindly treating patients by classes, as were. For the treatment of the fever of consumption he recommends rest, but recognizes the fact that in exceptional cases oftentimes a certain amount of exercise will tend to lower the temperature.

The author has evidently slight regard for medi-

cines in comparison with open-air treatment, and believes that pure air is more important than mere change of climate.

The appendix to the book contains the most approved methods of staining in examination for bacilli.

The book shows clearly the breadth of vision of the author, and abounds in practical useful suggestions both for general practitioners and for those who make a special study of the disease. It should be in the library of every sanatorium and of all who make a special study of consumption.

A Manual of Practical Hygiene for Students, Physicians and Medical Officers. By CHARLES HARRINGTON, M.D., Assistant Professor of Hygiene in the Medical School of Harvard University. Illustrated with 12 plates and 105 engravings. Philadelphia and New York: Lea Brothers & Co. 1902.

The demand for a second edition of this serviceable work in a very short time after its first appearance is in a great measure a proof of its excellence.

The volume will be found very useful to students in hygiene, to physicians, and especially to all persons who are interested in questions relating to the chemistry of food, with which the author's wide experience has made him very familiar.

The chapters on air, soil, water, disinfection and the hygiene of occupations are also very fully and clearly presented, and a chapter on the relation of insects to human diseases has been added, presenting a summary of the results of this recent addition to the literature of sanitary investigation.

The manual contains many useful plates and illustrations, together with valuable tables showing the composition of every kind of food used by man, the specific gravity of milk, the determination of alcohol in liquors, the relation of typhoid fever to the purity of water-supplies, etc., all of which add to the value of the book for the purposes of reference and as an aid to the study of hygiene.

Human Anatomy. A complete Systematic Treatise by various authors, including A Special Section on Surgical and Topographical Anatomy. Edited by HENRY MORRIS, M.A. and M.B. (Lond.), F.R.C.S. (Eng.). Illustrated by 846 woodcuts. Third edition, revised and enlarged. Philadelphia: P. Blakiston's Son & Co. 1902.

In this third edition of one of the recognized authoritative textbooks of anatomy, the editor has had the text revised when necessary, and alterations in the old or entirely new drawings substituted in many instances. The volume, as it now appears, comprises 1328 pages, including the index. The text is complete, the illustrations are eminently satisfactory, and the arrangement of the subject matter well adapted for ready reference. As a textbook of descriptive anatomy, this book stands with the best, and it contains certain useful facts which are not to be found in others of its general scope. There is no doubt that it will continue to deserve the appreciation with which it has been received, especially in England, and to a somewhat less extent in this country.

American Edition of Nothnagel's Practice. Diseases of the Pancreas, Diseases of the Suprarenal Capsules, and Diseases of the Liver. By L. OSER, M.D., Professor of Internal Medicine, Vienna; E. NEUSSER, M.D., Professor of Internal Medicine, Vienna, and H. QUINCKE, M.D., Professor of Practice of Medicine, Kiel, and G. HOPPE-SEYLER, Professor of Internal Medicine, Kiel. Edited, with additions, by REGINALD H. FITZ, M.D., Hersey Professor of the Theory and Practice of Physic, Harvard University Medical School, and FREDERICK A. PACKARD, M.D., late Physician to the Pennsylvania and to the Children's Hospitals, Philadelphia. Authorized Translation from the German, under the editorial supervision of ALFRED STENGEL, M.D., Professor of Clinical Medicine, University of Pennsylvania. Philadelphia, New York, London: W. B. Saunders & Company. 1903.

This volume of the American edition of Nothnagel's Practice is an illustrated octavo of 918 pages. The division devoted to the diseases of the pancreas takes about one third of the volume, 302 pages, thirty-two pages of which are occupied by a very thorough bibliography embracing not only references to authors mentioned in the text but also the references to the subject in general bibliographies. This in itself is a most useful offering to the investigator. Dr. Oser of Vienna had charge of the original article on the subject, to which Dr. Zuckerkandl added an introductory chapter on the descriptive and topographic anatomy of the pancreas, with especial reference to the clinical point of view. Dr. Oser's article exhibits all the thoroughness characteristic of so much German work, to which is added an acquaintance with and generous appreciation of the work of others, and especially of that of American and English writers. Since the publication of Dr. Oser's article some notable contributions have been made to the study of diseases of the pancreas, and particularly those from the surgeon's standpoint in regard to chronic pancreatitis and the influence of gallstones in the etiology of acute pancreatitis, in comparison with morbid conditions experimentally induced. Although the first word concerning the affections of the pancreas, as concerning those of the appendix and the gall bladder, came from medical men, the investigation of pathological conditions *in vivo*, which is the privilege of a well-guarded laparotomy, has permitted the surgeon to add materially both in theory and practice to the earlier suggestions of the physician.

For editor of the American edition no better choice than that of Dr. Fitz could have been made, whose name has already for some time been associated with the elucidation of this still somewhat obscure subject. His editorial contributions bracketed through the text exhibit the genuineness of his editorial supervision, and give the assurance that we have in this volume the latest words in regard to the affections of this important but long-neglected organ,—the pancreas. Some beautiful colored plates, reproducing specimens of pancreatic disease from the Warren Anatomical Museum at the Harvard Medical School, add much to the value of the article.

The second article, also edited by Fitz, is on the diseases of the suprarenal capsules, and was written by Neusser of Vienna; to it is appended a section on Addison's disease and a bibliography brought down apparently to 1896. Under the physiology of the suprarenal capsules the therapeutic properties of the materials yielded by the suprarenals receives due attention, and references to the literature on epinephrin, suprarenin and adrenalin down to 1902, as well as a discussion of the therapeutic properties of suprarenal extract, are given by the American editor.

The last 520 pages, or somewhat more than half of the volume, are taken up by an exhaustive monograph on diseases of the liver, of which the original German authors were Quincke and Hoppe-Seyler of Kiel, and the American editor was Dr. F. A. Packard of Philadelphia, whose untimely death some months since was much deplored by all who knew him. The most important and interesting recent additions to our knowledge of diseases of the liver have to do with cholelithiasis, and the surgical contributions to these must be acknowledged. As to questions of diagnosis and treatment in all conditions dependent upon or suspected of being dependent upon gallstones, it is most desirable that the physician and surgeon should co-operate with harmony and mutual appreciation. The American editor in his notes exhibits a thorough acquaintance with the work of the last few years in the subjects covered by the title of this monograph; the original text is worthy of the reputation of its authors.

Diseases of Women. A Clinical Guide to Their Diagnosis and Treatment. By GEORGE ERNEST HERMAN, M.B. (Lond.), F.R.C.P., Obstetric Physician to the Lecturer on Midwifery at the London Hospital, consulting Physician-accoucheur to the Tower Hamlets Dispensary, Examiner in Midwifery to the University of Cambridge and the Royal College of Physicians, Late President of the Obstetrical Society of London and of the Hunterian Society. Revised Edition. New York: William Wood and Company. 1903.

This volume of 884 pages is written in a most readable style by an Englishman with, as he says in the preface, clinical experience.

The subject is treated from the standpoint of the general practitioner and not from that of the operating specialist.

The contents consists of the following headings: General Chronic Pelvic Pain, Pelvic Inflammation, Internal Hemorrhage, Hemorrhage, Leucorrhea, Disorders of the Vulva, Disorders of Menstruation, Disorders of the Sexual Functions, Disorders of Parts Adjacent to the Sexual Organs, and Abdominal Tumors. From which it will be seen that the author arranges the maladies according to their leading symptom rather than anatomically, as in most works on gynecology.

The book is the work of a careful observer and clear, honest thinker, with a ripe clinical experience, and is a fair statement of gynecology as practised in England today.

The advice given to the student and practitioner is conservative and sound, and the work should prove a valuable addition to his library.

THE BOSTON
Medical and Surgical Journal
 THURSDAY, MAY 14, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE, (INCORPORATED),
 283 WASHINGTON STREET, BOSTON, MASS.

AMERICAN MEDICAL ASSOCIATION.

THIS is the season of medical meetings. By common consent the early spring seems to have been chosen for these general medical gatherings. There is the more reason for such meetings being held early, if, as is the case this year, two of the largest in America are held in Southern cities.

The American Medical Association has just completed one of the most successful meetings in its history at New Orleans. The prophecy of the appeal sent out by the local Committee of Arrangements in December of the charm of May in New Orleans has been amply verified. From the general character of the addresses, and from the character of the papers read at the meetings of sections, it is apparent that this organization is coming to be one of the great scientific and practical forces in medicine in this country. It is growing in numbers year by year; it is attracting the best men in all special branches; it sets no other standard of admission than a recognized, honorable position in the profession, and thereby brings together the rank and file of the profession as no other organization in America is at present doing. The association is coming more and more to stand for the best in medicine, not only on its scientific side, but also in its vastly important relations to the community and to governmental interests. It is clear that no other association now in existence can accomplish this latter purpose with the same degree of success as the American Medical Association. To the end that it may still further and more completely represent the best medical opinion, it should be urged upon physicians everywhere to join the association.

In his presidential address this year, published in the last issue of the JOURNAL, Dr. Frank Billings discussed at length the present somewhat deplorable state of medical education, and urged most forcibly

that our medical schools should be reduced in numbers and that their standards should be correspondingly raised. The plea he made does not lay claim to originality, but it is a matter which should yearly be brought in some form before medical men, to the end that a standard in medicine may be attained which will place us on an equality in this respect with foreign countries.

This meeting of the association in general will, no doubt, be remembered as a conspicuous example of what such meetings should be, in having brought to the front, not only strictly professional matters, but also other questions which intimately concern the medical profession in its relation to the general public.

THE CONGRESS OF AMERICAN PHYSICIANS
 AND SURGEONS.

THIS week sees another medical meeting in Washington, the membership of which is somewhat more limited than that of the American Medical Association, and which represents, to a certain degree, a different phase of medical progress. In looking over the program of these meetings, one is above all impressed with the vast diversity of subjects which are included in the proceedings of the Congress of American Physicians and Surgeons. Year by year new sections are added to this association, so that now sixteen more or less specialized fields in medicine are represented by individual organizations.

The latest addition to these special societies is the Association of Pathologists and Bacteriologists. Many of the leaders in this new society were already members of the Association of American Physicians, but the technicalities of pathological and bacteriological research have reached such a pass that there is a practical demand for separate consideration of the results attained. It is always interesting to speculate as to whither the future tendencies, represented by this congress, are to lead. It is, perhaps, melancholy to contemplate, but the fact is forced upon us already that in another ten years many of the subjects discussed in one section of the congress will be absolutely unintelligible to the others. We surmise that this state of affairs has already come to pass in a measure, as we look over the extraordinarily technical character of many papers presented at the sectional meetings. It all means progress, however, and we should never allow our fears for the narrowing tendencies of specialism to cloud our vision as to the ultimate advantages to which such specialized work leads.

Dr. W. W. Keen's presidential address, is worthy of more than passing mention. He discusses questions which are always of vital impor-

tance, and will remain so whatever the future trend of medicine may prove to be. This congress, like the meeting of the American Medical Association, must be regarded as one of the most successful in its rather brief history. The subjects discussed, the quality of the special papers presented, and the general conduct of the congress, permit a pardonable feeling of pride at the positive accomplishment which American medicine is making in the most varied fields of research.

THE DUTIES AND RESPONSIBILITIES OF TRUSTEES OF PUBLIC MEDICAL INSTITUTIONS.

INSTEAD of devoting his address as president before the recent Congress of American Physicians and Surgeons at Washington, as is usual, to some special professional topic, Dr. Keen, following the suggestion of members of the executive committee, gave the time at his disposal to the presentation of some thoughts on the above subject. Our readers will find the address in full in this issue of the JOURNAL, and we desire to direct attention to it, for the well-matured opinions of a man of Dr. Keen's experience and judgment on such matters merit due consideration.

The public medical institutions dealt with are, (1) medical schools and (2) hospitals, whether connected with medical schools or not. The class of medical institution of which the Rockefeller Institute for Medical Research is our single example is not included, for obvious reasons.

Dr. Keen thinks much is to be gained by inviting the medical board or staff, or if too large, a committee representing it, to the meetings of boards of trustees or managers, and thus bringing these bodies into more intimate contact.

He favors a fixed age of compulsory retirement, whether for professors in medical schools or for hospital physicians and surgeons. In his opinion sixty-five would be a suitable age limit. To obviate the premature loss of services of very exceptional men, boards of trustees might in special cases preserve to their institutions such men by extending the limit to seventy years, but in no case ought they to go beyond this limit.

A sabbatical year Dr. Keen regards as unnecessary for professors in medical schools. He thinks that a small proportion, about one fifth, of well-chosen medical men on boards of trustees of hospitals or medical schools is a distinct advantage. But it should be positively understood, if not indeed absolutely expressed, in institutions in large cities, at least, that any physician or surgeon placed upon such a board should never be eligible, even by

resignation from the board, for a position on the faculty or the medical staff.

As for trustees, their duties and responsibilities are not at an end when they have taken care of the funds and elected a staff, although that is a common opinion. It is their duty to see, by proper supervision of the staff, that the intellectual funds as well as the invested funds of the institution bring in good dividends.

MEDICAL NOTES.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, May 13, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 43, scarlatina 40, typhoid fever 19, measles 51, smallpox 0.

RECEPTION TO THE ASSOCIATION OF MILITARY SURGEONS. — Brig.-Gen. Robert A. Blood, surgeon-general of Massachusetts, has issued invitations for a reception to be given to the Association of Military Surgeons of the United States, on Tuesday evening, May 19.

REPORT OF THE STATE BOARD OF INSANITY. — According to the fourth annual report of the Massachusetts State Board of Insanity, it appears that the insane in public institutions, October 1, 1902, numbered 8,271, with a slight preponderance of women. These figures indicate a small increase over the preceding year, for which one of the reasons given is that the almshouses have cared for fewer patients. The overcrowding of the institutions for the insane still continues to be very great. Corridors and day rooms are in use for sleeping purposes, and the conditions cannot be improved without very material additions to the hospital facilities, necessitating generous appropriations.

RESEARCH AT THE BOSTON FLOATING HOSPITAL. — It is reported that special bacteriological work will this summer be done on the floating hospital in relation particularly to the etiology of dysentery. This work is undertaken under the auspices of the Rockefeller Institute for Medical Research, with the immediate advice of Dr. Theobald Smith. Arthur I. Kendall, Ph.D., a bacteriologist of experience, is said to be the choice for the position.

NEW YORK.

PROFESSOR OF PHARMACOLOGY AND THERAPEUTICS, COLUMBIA UNIVERSITY. — At a meeting of the trustees of Columbia University held May 4, Dr. Christian A. Herter, who is well known for his

work in original research, was appointed to the new chair, in the medical department, of pharmacology and therapeutics. He will be director of the laboratory of experimental pharmacology, soon to be established. Dr. L. Emmett Holt, professor of diseases of children, was assigned to a seat in the medical faculty. The students of the medical department have raised a fund of over \$450 to be devoted to the purchase of loving cups for the retiring professors, Drs. Weir, Peabody and Tuttle.

TUBERCULOSIS CAMP.—At a meeting of the board of health held May 6, President Lederle announced that he had decided to establish a tuberculosis camp on North Brother Island, in the East River.

BEQUESTS.—Among the bequests made by the late Charles S. Baylis of Brooklyn are \$10,000 to the Long Island College Hospital and \$2,000 to the Brooklyn Eye and Ear Hospital.

TYPHOID AT ITHACA.—On May 6 a senior in the engineering course of Cornell University died of typhoid fever at Ithaca. On that date two typhoid patients were discharged from the Cornell Infirmary, and it was stated that but two then remained under treatment.

EPIDEMIC INFLUENZA.—The bulletin of the State Department of Health for the month of March gives some account of the prevalence of epidemic influenza in the State during the past season. A few deaths from the disease were reported as early as October, but during that and the two months following the estimated mortality was not above 500. During January 1,200 deaths were attributed to it and during February 1,500, while the mortality was placed at about 2,000 for the month of March. The returns received for April up to the time the bulletin was issued indicated a decrease in the deaths from influenza.

POLLUTION OF PUBLIC WATERS.—The governor has signed a bill passed at the recent session of the legislature forbidding the pollution of public waters by commercial establishments or others in a manner detrimental to the public health. The jurisdiction on the matter is placed with the State Department of Health, by which permits for the discharge of materials from factories must be granted.

NEW YORK EYE AND EAR INFIRMARY.—The Schermerhorn Pavilion of the New York Eye and Ear Infirmary was opened Monday, May 11, with appropriate exercises. Bishop Potter, vice-president of the Infirmary, made an address, as did Rev. Mrs. Huntington and Green, Miss Keller, Dr. Gorham Bacon and others.

NOTES FROM THE PHILIPPINES.

ASSISTANT COMMISSIONER OF HEALTH.—The position of Assistant Commissioner of Health has lately been filled by the Philippines Commission by the appointment of Dr. Edward L. Munson, captain and assistant surgeon in the army. Dr. Munson has been stationed in Manila as assistant to the chief surgeon, and also as sanitary inspector of the buildings and watercraft controlled by division headquarters. He was assistant professor of hygiene and sanitary chemistry at the Army Medical School in Washington at its last session, and is the author of a large work on military hygiene, adopted as the standard textbook in the military services of the United States and other nations. He is thus exceptionally well qualified to fill the duties of the new position to which he has been appointed. It is understood that he will perform the duties of health officer for Manila.

PROHIBITION OF SALE OF INTOXICATING LIQUORS.—A matter of much importance to the health of the army here is the passage of a law by the insular government, in response to a request from the military authorities, prohibiting the sale of intoxicating liquors in the vicinity of seventeen large military posts and reservations. In most of the cases the sale of such liquors is prohibited within a distance of two miles from the limits of the military reservations. In some few cases this distance is reduced to one and one-half miles. In a few instances, where posts are in or on the outskirts of large towns, the liquor interests have been able to have these limits reduced to four or five hundred yards. With the abolition of the canteen, the soldiers have been driven to questionable resorts, which sprang up like mushrooms within a few yards of the military reservations, and a considerable increase in drunkenness, disorder and venereal disease has resulted. The new legislation is intended to offset the loss of the canteen, as far as possible, by driving away the saloons from the vicinity of posts and making it more difficult for the soldiers to patronize such resorts. Penalties for infractions of this law may be imposed to the extent of \$100 fine and six months' imprisonment for each instance, and for the proper enforcement of the law the commanding officers of the posts mentioned are given the powers of justices of the peace for the trial of civilians in such cases. The law will be a severe blow to the saloon men, many of whom have invested heavily near the new posts for the purpose of securing future trade. At one large post, about forty miles from Manila,—Camp Stotsenberg,—the saloon men had united to secure a large tract of land near the garrison, and just across the reservation lines, where they had built a small town, with

all kinds of vicious attractions for the soldiers. Much money was expended by the liquor interests in this town, as the post now under construction is to be a large, permanent garrison, and a strong fight has been made by the saloon men against the passage of the law. In this climate, and particularly in the rainy season, there is no question but that a walk of two miles out and two miles back, in addition to the day's work, will deter all but the steady drinkers. Of course plenty of people will be found who will smuggle liquor into the reservation, but a few severe sentences by post commanding officers will largely break up any such business. One great trouble in preventing liquor smuggling on army reservations in the United States was that commanding officers had no power to inflict punishment, and the sympathy of the surrounding civil population stood in the way of securing proper punishment of the offenders in the civil courts. The results of the new system will be watched with much interest by the military surgeons and the army officers generally.

A MODEL TENEMENT. — Following the removal of the unsanitary habitations of the squatters on government land near the water front, the city government has constructed a large tenement for their accommodation, rooms in which will be rented at about cost. As a sanitary experiment, the outcome will be watched with much interest. The number of occupants for each apartment is laid down, cleanliness must be maintained, game cocks and pet animals will not be allowed on the premises, nor can there be any sale of goods or food on the premises. A janitor will enforce these regulations. It remains to be seen whether the Filipinos are willing to give up their usual filthy habits and surroundings, and their cherished fighting cocks, for the sake of excellent accommodations and low rents.

RECONCENTRATION. — The political conditions in the provinces of Albay and Sorsogon are so disturbed that the civil authorities contemplate the establishment of the reconcentration policy there, to combat existing lawlessness and brigandage. Anticipating the occurrence of cholera and other disease among the natives under reconcentration, the Board of Health has prepared plans for the establishment and equipment of hospitals near the proposed points of concentration. These hospitals have an abundance of supplies and a sufficient medical and nursing personnel, who are already on the ground in case their service should be required.

ASSISTANT SANITARY ENGINEER. — To facilitate the projected sanitary improvements of Manila, the commission has recently created the position of assistant sanitary engineer, having a salary of \$3,000

per annum attached. Heretofore the sanitary engineer for the island has also been in direct charge of the sanitary improvements in Manila.

Miscellany.

BACTERIOLOGICAL IMPURITIES OF VACCINE VIRUS.

AN investigation on bacteriological impurities of vaccine virus, conducted by M. J. Rosenau, from the Hygienic Laboratory of the Public Health and Marine Hospital Service, reaches the following important conclusions:

All the samples examined were purchased on the open market, care being taken to buy unbroken original packages from reliable pharmacists who keep the product under proper conditions of light and temperature. With a few exceptions, the vaccine was examined before the time limit expired, if the time was given by the manufacturer.

Of 190 dry points examined we found an average of 4,354 bacteria per point. A number of these points contained over 15,000 and one as high as 44,000 organisms. Of 244 tubes of glycerinated virus examined we found an average of 1,742 bacteria per tube. A number of these capillary tubes contained over 10,000 bacteria and one as high as 30,000. This is, of course, much more than a carefully prepared glycerinated virus should contain.

We found the pus cocci and other bacteria, pathogenic for laboratory animals, in both the dry points and the glycerinated virus.

We have demonstrated that some of the glycerinated virus marketed during the winter of 1901-02 contained an excessive number of bacteria, which decreased notably after a few weeks, indicating the sale of a "green" or unripe product; that is to say, the virus was not glycerinated a sufficient length of time before it was sold.

It was also plain from our studies that too much confidence was placed by the producers in the germicidal power of glycerin.

The excessive impurities found in some of the glycerinated virus upon the market we believe was largely due to this overconfidence in the germicidal value of glycerin; operators become careless, trusting to the glycerin to purify their product. We know that glycerin is too feeble in its properties to purify vaccine matter which has initial contamination such as our work indicates.

After we called attention to this point we found a marked improvement in the glycerinated virus on the market. For instance:

During the winter of 1901-02 the glycerinated virus contained an average of 4,698 bacteria per tube.

In the spring (April and May) of 1902 the average fell to 1,058 bacteria per tube.

This winter (November and December), 1902, the average of 89 tubes examined was only 29 bacteria—maximum 239.

Glycerinated virus, when properly prepared and kept a sufficient length of time, is freer from impurities than dry points made with fresh "lymph."

There is practically no difference between the glycerinated virus dried upon ivory points and that hermetically sealed in capillary tubes, so far as bacteriological impurities are concerned.

It will be seen that there is practically no vaccine on the market free from bacterial contamination, although the product of some manufacturers is remarkably pure.

The unevenness of the purity of vaccine as marketed by some manufacturers is very marked. The greater contamination of the vaccine during the winter of 1901-02 may be accounted for, in part, by the undue haste and accompanying carelessness incidental to supplying the increased demand for vaccine virus at that period.

We have examined a great number of dry points and the contents of glycerinated tubes for tetanus, but have been unable to find the organism of this disease.

Tetanus spores may live a long time in vaccine virus. We have found them alive and virulent on dry points after 295 days, and in glycerinated virus sealed in capillary tubes 355 days.

Tetanus may become a contaminating element of vaccine before it leaves the heifer. During the period of three to five days which elapses between the vaccination of the heifer and the removal of the virus there is opportunity for tetanus to find a lodgment in the eruption on the heifer's body surface, provided tetanus is present in the stall or stable surroundings of the animal.

If tetanus reaches the heifer's vaccinated area it may contaminate both the "dry points," which are made directly from the "lymph," and also the vaccine pulp, which the manufacturer subjects, for a longer or shorter time, to the germicidal action of glycerin before he markets it as "glycerinated virus."

Tetanus added to glycerinated vaccine virus does not terminate when kept hermetically sealed and under anaerobic conditions in small capillary tubes. It gradually loses its virulence both in the tubes and on the ivory points. Although the virulence is lost, the tetanus spores are not necessarily dead; for, while they will not produce symptoms when inoculated directly into mice, they may be revived into active virulent cultures by growing in a fresh bouillon under favorable conditions; that is to say, the vegetability of the spore remains active long after it has lost its power to produce the disease when inoculated directly into mice.

Therefore, in looking for tetanus in vaccine virus it is best to make cultures first and study the growth for endospore bearing rods, and then test the effects of the culture on animals.

The spores of tetanus lose their virulence and die much more quickly in the vaccine lymph on dry points than in the glycerinated tubes.

The vitality of tetanus in glycerinated virus depends largely upon the number of spores contaminating the virus. Large quantities, namely, forty times the minimal lethal dose ($40 \times \text{MLD}$), remain alive and active over a year. Smaller amounts may disappear in four to seven months. Very small amounts ($1 \times \text{MLD}$) have in one of our experiments lost virulence in one month and failed to grow in bouillon in two months.

On the other hand, these very small amounts of tetanus may remain active for months in glycerinated virus in capillary tubes. In one instance as small a quantity as 0.00055 cc., which was about two and a half times the minimal fatal dose, remained active seven months.

In vaccinal "lymph" on dry points the spores may begin to lose their virulence in two weeks and be dead in four months. Usually they live longer. We found them alive and virulent in points that had been contaminated with $50 \times \text{MLD}$ about ten months (295 days).

Correspondence.

TUBERCULOSIS.

156 WEST CHIPPEWA STREET,
BUFFALO, May 11, 1903.

MR. EDITOR: Will you kindly allow me to present the following proposition through your columns? Without expressing a personal opinion, I would like to collate a series of clinicians, sanitarians and pathologists, and could suggest that, to insure their receipt, they be sent to me in the form of private correspondence or references to literature.

"Of all diseases due to parasites, of whatever kind, tuberculosis alone clearly illustrates predisposition by general states of the organism of the host, independently of opportunities for infection and of plainly local lesions of cellular states (as in regard to the malignant neoplasms, if these be considered parasitic) which favor colonization of the parasite. Even in the case of tuberculosis, these latter factors outweigh purely general conditions of diminution of resistance."

Very truly yours,

A. L. BENEDICT, M.D.

Deaths reported, 3,672; under five years of age, 1,033; principal infectious diseases (smallpox, measles, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 852. acute lung diseases 659, consumption 428, scarlet fever 56, whooping cough 38, cerebrospinal meningitis 10, smallpox 11, erysipelas 7, measles 65, typhoid fever 65, diarrheal diseases 78, diphtheria and croup 77.

From whooping cough, New York 9, Chicago 5, Philadelphia 7, Pittsburg 5, Providence 4, Boston 4, and Brockton, Taunton, Brookline and Westfield 1 each. From erysipelas, Chicago 1, Philadelphia 2, Boston 2, Salem 1, Pittsfield 1. From smallpox, Chicago 2, Philadelphia 4, Pittsburg 5.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending April 18 the death-rate was 15.9. Deaths reported, 4,698: acute diseases of the respiratory organs (London) 262, whooping cough 91, diphtheria 64, measles 165, smallpox 18, scarlet fever 27.

The death-rate ranged from 7.8 in Croydon to 24.4 in Sunderland; London 16.1, West Ham 12.6, Brighton 19.5, Portsmouth 15.0, Southampton 14.2, Plymouth 19.1, Bristol 17.4, Birmingham 18.3, Leicester 12.1, Nottingham 16.1, Bolton 17.1, Manchester 17.9, Salford 17.7, Bradford 15.8, Leeds 14.1, Hull 15.7, Newcastle-on-Tyne 17.1, Cardiff 12.1, Rhondda 20.0, Liverpool 18.3, Wigan 23.5.

METEOROLOGICAL RECORD.

For the week ending May 2, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

| DATE | Barometer. Daily mean. | Thermometer. | | Relative humidity. | | Direction of wind. | | Velocity of wind. | | We'th'r * | | Rainfall in inches. |

OFFICIAL LIST OF THE CHANGES OF STATION AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING MAY 7, 1903.

NYDEGGER, J. A., passed assistant surgeon. Bureau order of April 21, 1903, directing Passed Assistant Surgeon Nydegger to proceed to Gulf Quarantine and assume command of the service of that port, revoked. May 2, 1903.

FOSTER, M. H., passed assistant surgeon. Granted leave of absence for two days. May 4, 1903.

KERR, J. W., assistant surgeon. Granted leave of absence for two days from May 7. May 6, 1903.

BALLARD, J. C., acting assistant surgeon. Granted leave of absence for twenty days from April 23. May 2, 1903.

FRARY, T. C., acting assistant surgeon. Granted leave of absence for one day. May 5, 1903.

GRACE, J. G., acting assistant surgeon. Granted leave of absence for nine weeks. May 2, 1903.

MARR, H., acting assistant surgeon. Granted leave of absence for thirty days from May 10. May 2, 1903.

WOODS, C. H., pharmacist. Department letter granting Pharmacist Woods leave of absence for twenty days amended so as to be for nineteen days. May 2, 1903.

HOLT, E. M., pharmacist. Granted leave of absence for thirty days from May 5. May 2, 1903.

PROMOTION.

C. W. STEPHENSON, pharmacist of the third class, promoted to be pharmacist of the second class, effective April 1, 1903.

BOARD CONVENED.

Board convened to meet at the Marine Hospital, San Francisco, Cal., May 2, 1903, for the physical examination of an officer of the Revenue Cutter Service. Detail for the Board: Assistant Surgeon Carl Rannus, Chairman; Assistant Surgeon C. W. Vogel, Recorder.

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING MAY 9, 1903.

D. O. LEWIS, surgeon. Detached from the "Pensacola," and granted sick leave for three months.

H. SHAW, assistant surgeon. Ordered to the "Yankee."

P. L. COCKE, acting assistant surgeon. Detached from the Naval Academy and ordered to the "Chesapeake."

R. H. MICHELS, assistant surgeon. Ordered to the "Wisconsin."

H. F. STRINE, P. J. TRAYNOR, J. L. NEILSON, F. M. MUNSON, R. A. BACHMAN, assistant surgeons. Ordered to the Asiatic Station, via Solace.

T. A. BERRYHILL, surgeon. Detached from the Navy Yard, Pensacola, Fla., and ordered to the "Baltimore."

W. F. ARNOLD, surgeon. Detached from Port Isabela, P. I., and ordered to Naval Hospital, Yokohama, Japan.

R. K. McCLANAHAN, assistant surgeon. Detached from the Naval Station, Polloc, P. I., and ordered to the "Oregon."

J. W. BACKUS, assistant surgeon. Detached from the "Princeton" and ordered to the "Helena."

H. A. DUNN, assistant surgeon. Detached from the Naval Station, Cavite, P. I., and ordered to the Naval Station, Olongapo.

R. E. HOYT, assistant surgeon. Ordered to the "Texas."
B. T. JENNESS, assistant surgeon. Ordered to the "Indiana."

PUBLIC HEALTH AND MARINE HOSPITAL SERVICE EXAMINATION.

WASHINGTON, D. C., April 30, 1903.

A board of officers will be convened to meet at the Bureau of Public Health and Marine Hospital Service, 3 B Street, S. E., Washington, D. C., Monday, June 15, 1903, for the purpose of examining candidates for admission to the grade of assistant surgeon in the Public Health and Marine Hospital Service of the United States.

Candidates must be between twenty-two and thirty years of age, graduates of a reputable medical college, and must furnish at least two testimonials from responsible persons as to their professional and moral character.

The following is the usual order of the examinations: 1, Physical; 2, Oral; 3, Written; 4, Clinical.

In addition to the physical examination, candidates are required to certify that they believe themselves free from any ailment which would disqualify for service in any climate.

The examinations are chiefly in writing, and begin with a short autobiography of the candidate. The remainder of the written exercise consists in examination on the various branches of medicine, surgery and hygiene.

The oral examination includes subjects of preliminary education, history, literature and natural sciences.

The clinical examination is conducted at a hospital, and when practicable, candidates are required to perform surgical operations on a cadaver.

Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur.

For further information, or for invitation to appear before the Board of Examiners, address,

WALTER WYMAN,
Surgeon-General.

SOCIETY NOTICE.

NEW ENGLAND HOSPITAL MEDICAL SOCIETY. — A regular meeting of the society will be held at 3 Park Street, Boston, Mass., on Thursday, May 21, 1903, at 7.30 P.M. The meeting will be in charge of the Section on Medicine, Dr. Elizabeth T. Gray, chairman. Paper, Dr. Mary S. Holmes, Worcester Isolation Hospital: "The Present Status of Diphtheria." Discussion, Dr. Harriet E. Lathrop: "The Care of the Healthy Throat in Which the K-L Bacillus is Found; and What the School-Boards are Doing to Prevent the Spread of Diphtheria." Dr. Mary S. Packard: "Present Methods of Disinfection."

DR. AGNES C. VIETOR, Secretary,
Trinity Court, Boston.

RECENT DEATH.

JAMES A. ROACHE, M.D., of Brooklyn, N. Y., died on May 3. He was born in New York City in 1869, and was graduated from the Long Island College Hospital in 1891. At the time of his death he was an attending physician at St. Mary's Hospital, Brooklyn.

BOOKS AND PAMPHLETS RECEIVED.

The Diagnosis of Diseases of Women. A Treatise for Students and Practitioners. By Palmer Findley, B.S., M.D. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1903.

A Manual of Diseases of the Eye for Students and General Practitioners. By Clarence A. Veasey, A.M., M.D. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1903.

A Pocket Book of Infant and Childhood Dietetics, with Directions for the Home Modification of Milk. By A. B. Späth, A.M., M.D. Chicago: E. H. Colegrove. 1903.

Hygiene and Public Health. By Louis Parkes, M.D., D.P.H. (Lond. Univ.), and Henry Kenwood, M.B., D.P.H., F.C.S. Illustrated. Philadelphia. P. Blakiston's Son & Co. 1903.

The Elements of Pathological Anatomy and Histology for Students. By Walter Sydney Lazarus-Barlow, B.A., B.C., M.D. (Camb.), F.R.C.P. (Lond.) Illustrated. Philadelphia: P. Blakiston's Son & Co. 1903.

The Prevention of Disease. Translated from the German, with an Introduction by H. Timbrell Bulstrode, M.A., M.D. (Cantab.), D.P.H. In two volumes. New York: Funk & Wagnalls Co. 1903.

On the Pathology of Acute Rheumatoid Arthritis. By W. Hale White, M.D. Reprinted from Guy's Hospital Reports, Vol. LVII.

Transactions of the American Climatological Association. For the Year 1902. Vol. XVIII.

Original Articles.

A STUDY OF FIVE HUNDRED AND THIRTY-FOUR OPERATIONS UPON THE GALL BLADDER AND BILE PASSAGES, WITH TABULATED REPORT OF FIVE HUNDRED AND FORTY-SEVEN OPERATED CASES.¹

BY WILLIAM J. MAYO, A.M., M.D., ROCHESTER, MINN.,

Surgeon to St. Mary's Hospital of Rochester, Minn.

IN nature's defense against infection within the abdominal cavity there are three weak situations — the Fallopian tube, the appendix and the gall bladder. The first to gain an accepted surgical position was the infective lesions of the tube. The ease of diagnosis and the remarkable results of operative interference contributed largely to this result. The appendix, after much discussion, has also reached an assured place in surgery; but the gall bladder has been slow to receive that attention from the medical public which its importance deserves. The patient is usually along in years and often, by reason of degenerative lesions or adipose tissue, a poor subject for operative interference; and, again, death does not frequently come with that tragic suddenness which oftentimes marks appendicitis.

Like the appendix, the gall bladder is a dependent organ with a limited outlet, connected, although less directly, with the intestinal tract; but fortunately at a point in which the micro-organisms normally present are not so active. Both organs are liable to stone formation; but infections of the gall bladder are usually due to less virulent bacteria, and its better blood supply and distensibility equalizes that tension which is so fatal a characteristic of the inflamed appendix. Perforation and sudden death, therefore, are less frequent in diseases of the gall bladder.

As a cause of chronic distress and disability in adult life, however, diseases of the gall bladder are nearly equal in frequency those of the appendix. While in later years, the gall bladder undoubtedly takes first place. The inflammatory affections of the Fallopian tubes which gave such an impetus to pelvic and abdominal surgery have dropped to third place, with lesions of the stomach a close competitor. In St. Mary's Hospital in 1902 the relative proportion of these operations was: appendix 345, gall bladder 143, ovaries and tubes 98, stomach 77.

The 534 operations upon the gall bladder and bile passages which form the basis of the report were performed upon 518 patients with 19 deaths, a mortality of 3.5%. Of the total number, 510 were for gallstone disease, with a mortality of 3%. Considering stones in the gall bladder as uncomplicated, there were 208 cases with 2 deaths, a mortality of less than 1%. On the other hand, grouping as complicated, stones in the cystic duct, stones in the common duct, infections with and without stones and malignant disease, there were 326 cases with 16 deaths, a mortality of 5%. This is a most significant fact and offers a strong argument in favor of early operation. It has been said that of the 5 to 10% of adults who have gallstones, the large majority do not have symptoms. I am convinced

that many times we physicians do not recognize and attribute symptoms really present to their proper source in the gall bladder; we too often make an indefinite diagnosis of dyspepsia or indigestion.

The standard of measure in the diagnosis of gallstones is the "colic," yet this is but a small part of the clinical picture, and is readily diagnosed. Not so the chronic distress and stomach disturbance which the evolution of the pathological process so often develops. In the latter case, the victim goes the round of the reputable practitioners of medicine, and then, unrelieved, falls into the hands of the charlatan or patent medicine vender, until complications develop or a condition of encapsulation is established, subject to occasional attacks of regional inflammation.

That the large majority of adults with gallstones never suffer is true, yet these stones but "slumber," with the possibility of a painful awakening. Once "active" the chances of permanently regaining a condition of "rest" is not good, although the interval may last for years. Under normal conditions the bile has been supposed to be sterile; but it has been demonstrated that if collected in sufficiently large quantities, a few bacteria can be detected, and, as shown by Lartigau, it is possible that the necessary attenuation of the infective agents is produced by passage through the liver, and that stagnation of the infected bile in the gall bladder is the usual cause of the "stone building catarrh," rather than an ascending inflammation from the intestines through the ducts. A gall bladder containing stones is always infected, and when this organ once becomes restless from the irritation of its host, the chance of a complete reconciliation is improbable. In 19 cases we have found and removed unsuspected gallstones during an abdominal operation performed for another purpose, and in the light of the findings, an inquiry properly directed demonstrated that the majority of these patients had suffered at times, but that the trouble was attributed to another cause. In some of these cases marked contraction of the gall bladder or dense adhesions indicated that there had been at one time an active disease present. The truth is that there are varying degrees of gallstone activity, of which the form characterized by "colics" is the most noticeable for obvious reasons. Not only is the mortality in the uncomplicated cases low, but the operation as a rule is of the simplest character, — opening the gall bladder, removal of the stones and attachment of the fundus of the organ to the abdominal wall, with temporary drainage of the bile to the surface. Cholecystostomy not only effectually cures the condition, but by permanently elevating the fundus, the cystic duct is brought to the bottom of the cavity, and gravity drainage ensues in the future. It is probable that even in these cases cholecystectomy will be the indicated operation in the near future, as this operation can be performed with almost equal safety. The "ideal" operation, that is, complete closure of the gall-bladder incision, has been successful in many cases of slumbering gallstones accidentally found during an abdominal operation performed for other purpose.

This is a dangerous practice in active gallstone disease, as activity means an increased infection.

¹ Presented May 13, 1903, at the Sixth Triennial Congress of American Physicians and Surgeons.

As long as the stones do not become lodged either in the pelvis of the gall bladder (Hartman's pouch) or the cystic duct, the usual short colic is the chief symptom, and cholecystostomy is sufficient. If the stones are impacted in either situation the colic is replaced by a constant distress less acute but more continuous. The gall bladder becomes distended and its walls infiltrated with inflammatory products. In such cases, as a rule, the stones can be dislodged and brought up and out through the gall bladder, and an ordinary cholecystostomy performed; but occasionally an incision through the wall of the duct is necessary for relief of the impaction, followed by suture of the duct and cholecystostomy or ablation of the organ itself. Operation in 183 cases of stones impacted in the pelvis or in the cystic duct resulted in 6 deaths, a mortality of $3\frac{1}{4}\%$. This included, however, a number of cases of severe infections. Should the walls of the gall bladder have undergone marked changes, or angulation and stricture of the cystic duct, resulting in mucous fistula, seem a possible outcome, cholecystectomy is more certain to afford permanent relief. If the cystic duct is completely obstructed so that the gall bladder contains no bile, it is a simple operation to detach the organ from the liver and ligate with catgut at the base; but if the gall bladder participates in the biliary circulation in spite of the obstruction, it is not always wise to ligate the cystic duct, especially if there is a cholangitis present. Under such circumstances, if it is decided to remove the organ, the cystic duct should be left open for drainage of the bile to the surface. It is in this class of cases that we have, where possible, removed the fundus and the entire mucous membrane, the peritoneum and outer layers of the base of the gall bladder being retained to form a pouch, into which the end of a drainage tube can be securely fastened for the purpose of safely conducting the bile to the surface. In 75 cholecystectomies, either complete or with the modifications outlined, there were but 2 deaths. This does not include 23 cholecystectomies made in the course of other operations.

Kehr, Robson and all of large experience in gallstone surgery, unite in declaring that they have not known gallstones to re-form after operation, and this has been our experience. In our early work, it sometimes happened that stones would be discharged from the fistula subsequent to the operation or occasionally the outer opening would cicatrize before all of the calculi were discharged, and those retained gave rise to future colics, requiring secondary operations, not because the stones had re-formed, but because the primary operation had been incomplete.

It is the fond hope of the patient that the stones will pass down and out through the common duct, and not infrequently this is the case, but there are usually more behind. We have never operated upon a patient who has passed calculi that we have not found more in the gall bladder. The passing of a calculus, instead of being a reason for delay, is an indication for operation, as the next labor may miscarry and lodge the stone in the common duct, in which situation the results of operative interference are no longer certain on account of the attendant jaundice and infection of the common and hepatic ducts.

Surgery of the common duct has become a fairly safe operation, the mortality depending more upon the condition of the patient than any difficulties in the technique. This, of course, has some marked exceptions. To the late Dr. Davis of Alabama we owe the most important contribution to this subject. He both experimentally and clinically called attention to the necessity of freely draining the bile to the surface after common duct operation, and demonstrated that suture of the duct was usually unnecessary and occasionally harmful. This saved much time in a class of cases with general debility from jaundice and infections of the ducts, in which time is an element of great value. If the cystic duct is open, enabling the bile to readily flow outward through the gall bladder to the surface by means of cholecystostomy, suture of the common duct may be harmless, but not otherwise.

To Robson we owe great improvement in the technique of this operation, especially the sand bag under the back at the level of the liver, to tilt the costal margin outward and upward on the principle of a reverse Trendelenberg position. The incision of Bevan through the abdominal wall, as modified by Robson, in dispensing with the lower angle and carrying the upper limb close to the costal margin, enables one to draw the liver downward and outward, and straightens the angle of the cystic duct at the common duct. In this way, removal of common duct stones is rendered easy. In many cases the common duct is so dilated by stones impacted in the terminal portion that the finger can be easily introduced, and by aiding the extraction with counter-pressure with the other hand over the duodenum, the stone may be coaxied backward and out of the duct incision. The finger can be used in the same way in the hepatic ducts. In no other way in some cases can one be certain the ducts are free. In a few cases, incision of the duodenum and direct extraction as advised by McBurnery may be necessary.

We had two such cases in our earlier experience. The "ball-valve" stone, so graphically described by the late Christian Fenger, was met with nine times. Kehr has extended the usefulness of hepatic drainage by direct tubage of the hepatic duct, and has shown us how to cure some cases heretofore considered hopeless. Out of the 534 cases we had 58 of stones in the common duct, with 3 deaths, $5\frac{1}{2}\%$. The relative proportion of common duct cases was 11% of the whole, considerably less than in either the Kehr or Robson series, who report a percentage of nearly 20%. Even 11% is too high. Gallstones should, in the large majority of instances, be diagnosed and sent to the surgeon before common duct symptoms clinch the diagnosis and force operation upon the patient.

Chronic pancreatitis, shown by enlargement of the head of the pancreas, was met with in connection with gallstone disease eighteen times. In six of these patients, cholecystoduodenostomy was performed, and all of these cases recovered. In the remaining twelve cases no special treatment beyond the removal of the gallstones and establishment of drainage was adopted. One case of acute pancreatitis and fat necrosis, due to a cholecystitis from one large gallstone in the gall bladder, recovered

operation, as did one subacute hemorrhagic st of the pancreas from the same cause.

It has been noted experimentally that high grades infection seldom cause stones, although these fections are most liable to occur in patients who ready suffer from calculi. In the acutely infected cases gangrene or perforation of the gall bladder may happen. In the more chronic infections of this type the symptoms are almost identical with gallstones. In 534 cases we had 27 of this chronic character with 3 deaths. The mortality at once demonstrates that the infection was more virulent than in gallstone disease. The deaths were usually from that condition called by Eisendrath "hepatary," or cessation of liver function, which the experimental work of Adami helps us to appreciate. These cases of chronic cholecystitis are very interesting because of the liability to overlook the condition at operation, on account of the absence of gallstones, although the gall bladder shows evidences of trouble.

In the benign series it is to be noted that 16 cases came to secondary operation, 14 were cured by the second operation, 2 required several operations before cure resulted. The average stay in the hospital was slightly less than three weeks, the attempt being to remove all of the stones at the primary operation and make the drainage more efficient by accurate placing and retention with tight sutures, which are absorbed before it is necessary to remove the drains. This reduces the quantity of packing to a minimum and enables primary closure of the wound without marked hernia liability. The sutures closing the abdominal incision are left in place two weeks, which makes it quite safe to allow the patient to get about early, an important factor in the recovery of old people. If the patient is cholemic, we give chloride of sodium as a prophylactic against hemorrhage. Otherwise we have not found a special preparatory treatment to be of value beyond the ordinary preparation for laparotomy. The after-care is very simple. If possible the bile is conducted into a bottle, and the drainage packing is not disturbed until the end of the first week, and after removal of the drains, repacking is rarely necessary. In severe cases, bile drainage to the surface is essential, and for this purpose the cystic duct, if unobstructed, offers an easy and safe avenue of escape from the hepatic ducts. In but few cases have we used direct incision and tubage of the common duct, as recommended by Kehr, advantageous.

Malignant disease of the gall bladder and bile ducts was met with twenty-four times, or 4% of the total number of cases. The proportion was about four times in the gall bladder to once in the ducts. In some cases the exact origin could not be determined by a reasonable exploration. Five times the gall bladder was removed for cancer. In two of these cases a considerable portion of the liver was also removed. Three patients are alive, one nearly two years, but unfortunately with recent recurrence of obstructive jaundice. In one case a carcinoma involving the terminal end of the common duct was removed by the duodenal route; recurrence after one and one-half years necessitated cholecystectomy.

As the presence of gallstones occurs in only 15%

of secondary cancers of the gall bladder and in over 90% of primary cancers, we must conclude that they are the chief etiological factor in the production of malignant disease of this organ. In nearly all of our cases gallstones were present and a clear history of active trouble could be elicited, although there may have been years of quiet between the colics and the development of the cancer. While the possibility of cancer could not be of itself considered an indication for the removal of gallstones, it is worth considering, as about one case in twenty-five coming to the operating table in this series had malignant disease. The usual precancerous condition would seem to be a gall bladder with thickened walls, due to chronic infection and calculi. It is just this class of gall bladders which are now being subjected to excision rather than drainage, and it is probable that in the future many cases of cancer will be removed in an early stage with permanent cure.

Palliative operations for malignant disease of the gall bladder and bile ducts are not of great service. In a few cases of common-duct obstructions, cholecystenterostomy gives relief for a time, and if the duodenum cannot be easily reached, the transverse colon serves as well for the purpose of anastomosis.

In five cholecystenterostomies for malignant disease, four were attached to the transverse colon, with one death, and in one to the duodenum. In non-malignant disease we attach to the duodenum, if possible, the Murphy button being used in all.

As an appendix to this paper is attached a statistical table which can be studied by those interested in the subject.

A TABLE OF FIVE HUNDRED AND FORTY-SEVEN OPERATIONS UPON THE GALL BLADDER AND BILE PASSAGES (MORE THAN ONE OPERATION PERFORMED AT ONE TIME, ONLY THE MAJOR IS TABULATED) OCCURRING IN ST. MARY'S HOSPITAL OF ROCHESTER, MINN., FROM JUNE 24, 1891, TO MAY 13, 1903.

St. Mary's Hospital reports, 527; Minnesota State Hospital and Private Practice, 20.

THE GERMICIDAL ACTION OF ALCOHOL.

BY CHARLES HARRINGTON, M.D., BOSTON.

Assistant Professor of Hygiene, Harvard Medical School,

AND HAROLD WALKER, M.D., BOSTON.

Assistant in Hygiene, Harvard Medical School.

THE discrepant results which different investigators have obtained in studying the disinfectant properties of alcohol, and the fact that ordinary commercial alcohol (94% by volume) and absolute alcohol (99% by volume) are used very extensively as skin disinfectants, particularly in the practice of vaccination and in several of the processes followed in attempting to ensure sterility of the hands in the practice of surgery, suggested to us the advisability of determining the germicidal properties of different concentrations against some of the more common pathogenic bacteria, with different periods of direct contact.

Before reporting our own results, a brief *résumé* of the more important investigations already published and an outline of the history of alcohol as a disinfectant are in order.

Alcohol has long been known as an efficient preservative of organic matter, and has been employed as a local application in surgery from time immemorial. Its disinfectant properties were studied first by Koch and his associates, who used as test objects anthrax spores, which were exposed to the action of different concentrations for weeks at a time, with no result. In his elaborate report on disinfectants, Koch¹ speaks incidentally of absolute alcohol and sterilized water as indifferent liquids ("... indifferente Flüssigkeit, z. B. durch sterilisiertes Wasser, absoluten Alkohol, u. s. w."). Not until 1888 was alcohol brought forward as an agent in producing sterility of the hands, and then it was recommended by Fürbringer² for the removal of fatty matters from the skin and consequent promotion of penetration of aqueous solutions of carbolic acid or of corrosive sublimate to the deeper parts.

In 1894 Reinicke³ announced that not only does alcohol remove fatty matters and thus promote penetration of disinfectants to the deeper parts, but acts also as a germicide; and Petruschky,⁴ in the report of his investigations of infection by pyogenic cocci, asserted that disinfection of the skin by means of ether and alcohol was not only possible, but easy of attainment. Krönig,⁵ however, failed in his attempt to kill dried *Staphylococcus pyogenes aureus* with 96% alcohol in five minutes, although he was successful in less time with the moist organisms, and stated his belief that alcohol, through its astringent action and by the withdrawal of moisture, causes bacteria to be held in the shrunken particles of skin.

The first important investigation of the subject was made by Epstein,⁶ who experimented with *B. pyocyaneus*, *B. prodigiosus* and *Staph. pyogenes aureus*, dried on silk threads for from one to four weeks, and then exposed to the action of six different concentrations of alcohol for periods

of three, five and ten minutes. He found that a preliminary wetting of the threads with water was essential to favorable results; but success was by no means constant. Epstein was followed by Minervini,⁷ who employed *Staph. pyogenes aureus*, *B. pyocyaneus*, *B. coli communis*, *B. subtilis* and anthrax spores, all dried on silk threads and on needles, which were exposed to five concentrations of alcohol at ordinary and boiling temperatures and, under pressure, at higher temperatures. His results led him to conclude that alcohol has, in general, a very slight bacterial influence, and that the best effects are attained by the use of concentrations of 50 and 70%.

In this he was in accord with Stremberg, who found that alcohol was effective against some species and powerless against others, no matter what strength was used, and that against the species which were affected, different concentrations acted with varying power.

Minervini's findings were corroborated by those of Bertarelli,⁸ who employed 25, 50, 70, 80 and 99% alcohol against *B. prodigiosus*, *B. pyocyaneus*, *Staph. pyogenes aureus*, *Sp. cholerae*, *B. pestis*, *B. typhosus* and anthrax spores, all dried on silk threads. His conclusion was that the most effective strength is 50%, which, however, must be considered as hardly entitled to a position above mediocrity. Salzwedel and Elsner⁹ experimenting with dried *Staph. pyogenes aureus*, found 55% alcohol to be the most efficient of the several concentrations used and inferior to 1:1000 corrosive sublimate. Absolute alcohol was found to be inert against dried bacteria, even after an exposure of days, although very efficient against those acted upon in a moist state.

The experiments of W. von Brunn¹⁰ with the vapors of varying strengths of alcohol against very richly sporing agar cultures of anthrax demonstrated that, whereas those of 51% and 74% alcohol at 79° C. were very effective within a few minutes, that of 95% alcohol produced no result at the end of an hour, and hence that the water present must be credited with playing a very essential rôle. Frank¹¹ obtained the most satisfactory results with vapor from 40% alcohol (boiling point 90° C.), with which he destroyed anthrax spores in five minutes. The vapors of 50 and 80% alcohol were also effective, but those of 90 to 99% and of weaker strengths than 40% were ineffective.

In the experiments of Weigl,¹² who found that 80 and 90% alcohols show greater bactericidal power than lower concentrations, bouillon cultures of *Sp. cholerae* and *Staph. pyogenes aureus* were mixed directly with different amounts of absolute alcohol, and then the influence of constant shaking in the thermostat was determined. In the tubes which were incubated at rest, coarse coagula were observed, while in those which were shaken the coagula formed were very fine. Naturally, the best results were yielded by the latter; but in problems of disinfection it is of no great importance to ascertain whether under special conditions a substance may act as a germicide, but rather whether

¹ Mitthell. a. d. kaiserlichen Gesundheits-, 1881.² Untersuchungen und Vorschriften über die Desinfection der Hände des Arzts, Wiesbaden, 1888.³ Centrallbl. für Gynäk., 1894, No. 47.⁴ Zeitschr. für Hyg. u. Infectiouskrankh., xvii, p. 59.⁵ Centrallbl. für Gynäk., 1894, No.⁶ Zeitschr. für Hyg. u. Infectiouskrankh., xxiv, p. 1.⁷ Zeitsch. für Hyg. u. Infectiouskrankh., xxix, p. 117.⁸ Il Policlinico, Oct. 1, 1900, p. 488.⁹ Berl. klin. Woch., 1900, No. 23, p. 496.¹⁰ Centrallbl. für Bakteriologie, xxviii, 1900, p. 309.¹¹ Munch. med. Woch., 1901, No. 4, p. 134.¹² Archiv für Hyg. xlv, 1902, p. 273.

der ordinary conditions of practice it may so act. experiments with threads impregnated with uillon cultures of *Staph. aureus* or with pus elded conflicting results, which cannot be regarded favorable to the practical application of alcohol surgical technique.

In planning our own experiments we determined employ a wider variety of pathogenic organisms, ich include those generally recognized as weakly, oderately and strongly resistant to chemical dis- ectants, and, in both the moist and dried condit- ons, to test their resistance to 15, 20, 25, 30, 40, , 60, 70, 75, 80, 85, 90, 94 and 99% alcohols, osing them for periods of varying duration. In e first series of experiments these were of 5, 10, , 30 and 45 minutes, 1, 2, 7, and 24 hours; in e second series, the species which had been found e destroyed within 5 minutes by certain of the eparations were exposed again for periods of 1, 3, 4 and 5 minutes, and three different cultures each organism were so tested.

The cultures employed were grown for 24 hours bouillon from 48-hour-old agar cultures kindly rurnished by Prof. H. C. Ernst. The bacteria re exposed to the alcohols on silk threads, which re introduced into the bouillon at the time of e inoculation. The threads were used partly in the moist state on withdrawal from the bouillon, and rtly after being dried at incubator temperature 48 hours. The experiments were conducted at mm-temperature. After being immersed for the quired time the threads were withdrawn from e alcohol, then planted in tubes of sterile bouillon, d incubated for 24 hours or longer at 37° C.

The results of the various experiments are pre- tated below in tabular form. Growth is indicated + and sterility by —.

| BACILLUS COLI COMMUNIS (Dried). | | | | | | | | | |
|---------------------------------|------------------|-------|-------|-------|-------|------|------|------|-------|
| ALCOHOL. % | TIME OF EXPOSURE | | | | | | | | |
| | 5 m. | 10 m. | 15 m. | 30 m. | 45 m. | 1 h. | 2 h. | 7 h. | 24 h. |
| 15 | + | + | + | + | + | + | + | + | + |
| 20 | + | + | + | + | + | + | + | + | + |
| 25 | + | + | + | + | + | + | + | + | + |
| 30 | + | + | + | + | + | + | + | + | + |
| 40 | + | + | + | + | + | + | + | + | + |
| 50 | + | + | + | + | + | + | + | + | + |
| 60 | + | + | + | + | + | + | + | + | + |
| 70 | + | + | + | + | + | + | + | + | + |
| 75 | + | + | + | + | + | + | + | + | + |
| 80 | + | + | + | + | + | + | + | + | + |
| 85 | + | + | + | + | + | + | + | + | + |
| 90 | + | + | + | + | + | + | + | + | + |
| 94 | + | + | + | + | + | + | + | + | + |
| 99 | + | + | + | + | + | + | + | + | + |

From the above we observe that dryness has a st important influence, for while the moist organ- isms are destroyed within five minutes by every length above 50 %, the dried are affected within same time by only 50 and 60 %, and show a

progressive resistance to the action of the stronger preparations, the two highest of which are abso- lutely inert even with 24 hours' contact.

In the second series of experiments three cultures were exposed in the moist state to 50 and 60 % alcohols for periods of one, two, three, four and five minutes, and in not one instance did growth occur; but the dried bacteria, exposed to 50, 60 and 70 %, yielded results which indicate that the strongest of the three concentrations was the slow- est in action, and also that the several cultures dif- fered slightly in resistance.

| 99 | + | + | + | + | + | + | + | + | + | |

B. typhosus, as is well known, is destroyed by chemical disinfectants much more easily than the pyogenic cocci, and the results obtained were not wholly unexpected. But from what has been written concerning the injurious effect of dryness on vitality it was not to be supposed that it would offer so much resistance in the dried state to the other concentrations.

The second series yielded results which indicate that the three cultures employed were, as was the case with the *Staph. aureus*, less easily killed than that used in the first. But it is interesting to note that the dried bacteria yielded more quickly than the moist to the influence of 30% alcohol.

B. diphtheriæ appears to be about equally resistant with *B. typhosus* in the moist state and considerably less to the stronger concentrations when dried.

In the second series the results obtained, using 40% alcohol, were practically the same as with *B. typhosus*, but the comparison cannot be carried farther because 50% alcohol was tried in place of 30%. The results follow:

BACILLUS ANTHRACIS.

The results obtained with this organism need no tabulation, for it is sufficient to say that, as has been demonstrated repeatedly by Koch and others, alcohol of any strength whatever has absolutely no influence against it. Every tube showed luxuriant growth within twelve hours.

CONCLUSIONS.

(1) Against dry bacteria, absolute alcohol and ordinary commercial alcohol are wholly devoid of bactericidal power, even with twenty-four hours' direct contact, and other preparations of alcohol containing more than 70%, by volume, are weak in this regard, according to their content of alcohol,—the stronger in alcohol, the weaker in action.

(2) Against the commoner, non-sporing, pathogenic bacteria in a moist condition, any strength of alcohol above 40%, by volume, is effective within five minutes, and certain preparations within one minute.

(3) Alcohol of less than 40% strength is too slow in action or too uncertain in results against pathogenic bacteria, whether moist or dry.

(4) The most effective dilutions of alcohol against the strongly resistant (non-sporing) bacteria, such as the pus organisms, in the dry state, are those containing from 60 to 70%, by volume, which strengths are equally efficient against the same organisms in a moist condition.

(5) Unless the bacterial envelope contains a certain amount of moisture, it is impervious to strong alcohol; but dried bacteria, when brought into contact with dilute alcohol containing from 30 to 60% of water by volume, will absorb the necessary amount of water therefrom very quickly, and then the alcohol itself can reach the cell protoplasm and destroy it.

(6) The stronger preparations of alcohol possess no advantage over 60 to 70% preparations, even when the bacteria are moist; therefore, and since they are inert against dry bacteria, they should not be employed at all as a means of securing an aseptic condition of the skin.

(7) Provided the skin bacteria in the deeper parts can be brought into contact with disinfectants, alcohol of 60 to 70% strength may be depended upon usually, but not always, to destroy them within five minutes.

REPORT OF FIVE CASES OF FRACTURE OF THE HIP IN CHILDREN.¹

BY H. M. CHASE, JR., M.D., BOSTON.

NOTWITHSTANDING the general impression in regard to the rarity of fractures of the neck of the femur in children, there have been a sufficient number brought to our attention, through reports of cases, to lead us to consider that this form of injury, though relatively infrequent, considering the large number of fractures of all types, is in reality more common than is appreciated; and a fracture which has been regarded as coincident with adult life and old age is found in childhood in a surprising number of cases, which would undoubtedly be increased if cases of apparently slight injuries to the hip were more carefully examined and the results interpreted with the aid of modern appliances for the study of bone surgery.

CASE I.—On Sept. 5, 1902, the patient, a girl of thirteen years of age, gave a history of dull pain in the left thigh below the groin, which commenced in April, 1902. History of previous good health. One month later the pain was so severe that she fell while walking; since that time she has had dull pain on motion, being free from it when quiet. At that time she was being treated for nervousness, and was in bed for four weeks; upon getting up a limp was noticed, she complained of slight pain at times, and she resorted to the use of crutches for ten

Fig. 1

weeks. General condition good. Left leg shortened 1.5 cm., atrophy of left thigh 3.5 cm., atrophy of calf .5 cm. Patient walks with left leg rotated outward, possibly inward rotation of 10°. Abduction limited, adduction resisted. Skiagram showed fracture of the neck of

the femur with considerable depression of the angle, illustrated in tracing Fig. 1.

CASE II.—On March 23, 1901, a girl of eleven years, perfectly well up to seven months ago, complained of weakness and attacks of pain in her left leg; she stated that the leg would "give out" when standing. No injury recalled at this time. Physically a very stout girl, who had gained rapidly in weight. Examination of spine negative. Left leg rotated outward, motions of knee and ankle normal. Motion of left hip in flexion 45°, in abduction 30°; practically no atrophy of thigh or calf. On April 15, 1901, very little change. On May 18, 1901, motions unchanged; a photograph which was taken three years ago confirms the report that there was no eversion of the left leg at that time. Patient now recalls that she had a fall from her bicycle, and one from a wharf two years ago, which agrees in respect to time with the duration of her symptoms; but she apparently sustained no injuries. In June, 1901, a skiagram suggested an old fracture of the femoral neck. In July, 1901, motion in flexion of the hip is free; no abduction possible; tires easily. Jan. 18, 1902, good general condition; shortening of left leg 1 cm., flexion to extreme possible limit with slight abduction; outward rotation free, inward rotation limited. Sept. 20, 1902, maximum shortening 1 cm., motions very much freer, dips a little in walking; shoe raised 1 cm. The skiagram of this case suggested an impaction of the neck near its junction with the shaft, which, however, was not definite; the history is suggestive and interesting, but one cannot be dogmatic in distinguishing it from coxa vara.

CASE III.—Boy, sixteen years of age, previously well, fell into an elevator pit about Feb. 1, 1900. He had severe pain in his hip, and was unable to walk for several weeks; was in bed with extension. Left leg shortened 2.3 cm., atrophy of thigh 1.3 cm., atrophy of calf 1 cm.; inward rotation of the hip limited, without spasm. Left trochanter 2.5 cm. above Nélaton's line; right tro-

Fig. 2

chanter on Nélaton's line. March 21, 1901, for seven months the patient has been working in a factory. Left leg flexed and abducted 15°; shortening of left leg 5 cm., atrophy of thigh 1.3 cm., atrophy of calf 1.5 cm. Left trochanter 5.5 cm. above Nélaton's line. Skiagram showed a fracture of the femoral neck. Tracing Fig. 2 shows considerable distortion of the pelvis, with line of fracture through the femoral neck near its junction with the shaft.

CASE IV.—Boy, fifteen years old; history of father having died of lung trouble seven years ago. Mother and brothers well. The patient has always been perfectly well; he was stout until the present year, when he began to grow tall. In April, 1902, when playing ball, he noticed a weakness of his left leg, apparently without any preceding injury. He was lame, and was obliged to use a cane, which permitted him to be up and about. Appetite good, sleeps well, no cough nor pain at

¹ From the Orthopedic Department of the Carney Hospital.

light. He complained of occasional soreness in the left groin, but was not confined to his bed. There was no pain till two weeks ago, when pain started in his groin, extending towards the hip joint and occasionally towards his knee. Heart and lung examination negative; abdomen negative; knee jerks exaggerated, no ankle clonus. Hip flexible. Right leg normal. Shortening of left leg 4 cm., apparent shortening 4 cm., atrophy of thigh 1 cm., atrophy of calf 1 cm. Slight thickening about the trochanter, no permanent flexion, permanent adduc-

ing rapid increase in weight, the occurrence of fracture from slight trauma, and the possibility of relatively slight disability following fracture of the femoral neck. They emphasize the fact that the bone may be fractured, giving rise to slight symptoms, the pain developing a number of weeks or months afterwards without known cause; and that depression of the femoral neck from fracture predisposes to further depression and a consequent gradual increase of disability. In contrast to the effects of fracture of the femoral neck in later life, we see in childhood less marked immediate effects while the remote effects are more disabling; and if recent cases of fracture pass unrecognized, danger lies in confounding their late results with hip dis-

he causes and of such great (much as the) orted by Dr.

the femur with considerable depression of the angle, illustrated in tracing Fig. 1.

CASE II.—On March 23, 1901, a girl of eleven years, perfectly well up to seven months ago, complained of weakness and attacks of pain in her left leg; she stated that the leg would "give out" when standing. No injury recalled at this time. Physically a very stout girl, who had gained rapidly in weight. Examination of spine negative. Left leg rotated outward, motions of knee and ankle normal. Motion of left hip in flexion 45°, in abduction 30°; practically no atrophy of thigh or calf. On April 15, 1901, very little change. On May 18, 1901, motions unchanged; a photograph which was taken three years ago confirms the report that there was no eversion of the left leg at that time. Patient now recalls that she had a fall from her bicycle, and one from a wharf two years ago, which agrees in respect to time with the duration of her symptoms; but she apparently sustained no injuries. In June, 1901, a skiagram suggested an old

chanter on Nélaton's line. March 21, 1901, for seven months the patient has been working in a factory. Left leg flexed and abducted 15°; shortening of left leg 5 cm., atrophy of thigh 1.3 cm., atrophy of calf 1.5 cm. Left trochanter 5.5 cm. above Nélaton's line. Skiagram showed a fracture of the femoral neck. Tracing Fig. 2 shows considerable distortion of the pelvis, with line of fracture through the femoral neck near its junction with the shaft.

CASE IV.—Boy, fifteen years old; history of father having died of lung trouble seven years ago. Mother and brothers well. The patient has always been perfectly well; he was stout until the present year, when he began to grow tall. In April, 1902, when playing ball, he noticed a weakness of his left leg, apparently without any preceding injury. He was lame, and was obliged to use a cane, which permitted him to be up and about. Appetite good, sleeps well, no cough nor pain at

ght. He complained of occasional soreness in the left groin, but was not confined to his bed. There was no pain till two weeks ago, when pain started in his groin, extending towards the hip joint and occasionally towards his knee. Heart and lung examination negative; abdomen negative; knee jerks exaggerated, no ankle clonus. Hip flexible. Right leg normal. Shortening of left leg 4 cm., apparent shortening 4 cm., atrophy of thigh 1 cm., atrophy of calf 1 cm. Slight thickening about the trochanter, no permanent flexion, permanent adduc-

tion of 15°. Slight motion in flexion, very slight motion in abduction, adduction and rotation; considerable eversion. Left trochanter 5 cm. above Nélaton's line. Tuberculin tests were repeatedly negative. Skiagram shows fracture of the neck of the femur with marked displacement. Tracing Fig. 3.

CASE V. — Boy, age sixteen. Family history unknown. Double from hip dates from child's earliest memory. No history of pain nor discharging sinus. Has always been lame and is easily fatigued, but can do light farm work. In April, 1902, sudden pain in left hip upon waking in the morning, located in region of trochanter; was very severe for two days, and then gradually disappeared. He used a cane during that time. There has not been a recurrence, but he tires easily. *Physical examination.* — Poorly nourished boy, dull, vacant expression. Cerebrated rather slowly. Phlyctenular keratitis over middle of right eye, obscuring vision, but not cutting off sensation of light. Examination of heart, lungs and abdomen negative. Cervical and inguinal glands palpable. Scar of old sinus close to the anus on the left side, also a scar in the left groin. Knee jerks present, no ankle clonus nor Babinsky. Right side of rotum enlarged to triple the normal size. Right testis enlarged and nodular, not painful. Right leg normal. Left leg held in position of permanent flexion about 15°, with free motion in flexion of 45°; 20° of adduction, no abduction. Outward rotation present to a considerable degree, slight laudosis. Leg not painful on manipulation. Shortening of left leg 3 cm., atrophy of left thigh 1 cm. X-ray shows coxa vara, with a transverse fracture of the femoral neck. On Dec. 19 subtrochanteric osteotomy was performed — the leg being dressed in plaster paris spica, in slight flexion and 15° of abduction. General condition excellent. The accompanying reproduction of the skiagram gives a clear idea of its condition. (Illustration Fig. 4.)

These cases emphasize the early age at which the fracture occurs, the possibility of fracture follow-

ing rapid increase in weight, the occurrence of fracture from slight trauma, and the possibility of relatively slight disability following fracture of the femoral neck. They emphasize the fact that the bone may be fractured, giving rise to slight symptoms, the pain developing a number of weeks or months afterwards without known cause; and that depression of the femoral neck from fracture predisposes to further depression and a consequent gradual increase of disability. In contrast to the effects of fracture of the femoral neck in later life, we see in childhood less marked immediate effects while the remote effects are more disabling; and if recent cases of fracture pass unrecognized, danger lies in confounding their late results with hip disease.

It is of interest to mention briefly the causes and symptoms of this condition, which is of such great importance to diagnose, especially inasmuch as the present method of treatment as reported by Dr. Royal Whitman in the *Annals of Surgery* for November, 1902, is in favor of disregarding the established idea of not interfering with impacted fractures of the femoral neck, and to correct the deformity at once.

The causes of fracture of the femoral neck are divided into the indirect, or predisposing, and the direct causes. Of the former may be mentioned relative slenderness of the bone, osteoporosis, osteomalacia, rachitis, osteomyelitis, tuberculosis and great increase in weight. Old age is predisposing toward fracture, though childhood is not exempt; also diminished obliquity of the neck of the femur and prominence of the trochanter major, by which the fracturing force is transmitted directly to the femoral neck. The direct cause of fracture is trauma, applied in the vertical direction through the axis of the femur, or force applied in the horizontal direction over the trochanter major, in the axis of the neck, or by traction force transmitted through the capsular ligament when the limb is forcibly hyperextended, abducted and rotated outward.

The symptoms of fracture are subjective and objective; the former are pain which varies very much, depending on the amount of trauma, laceration, irritation or inflammation, and impairment of function which may be slight or considerable. Objective symptoms may be swelling, ecchymosis, eversion, shortening, change of position of trochanter major, decreased mobility of the hip joint, painful change of position from the erect to the sitting posture, and loss of tension of the fascia between the crest of the ilium and the trochanter major.

Diagnosis of fracture of the femoral neck cannot be made from any one symptom, and a group of symptoms may so vary in detail as to make the diagnosis extremely difficult. The examination should be made carefully and thoroughly, weighing the clinical history with the result of examination, verifying the possibility of conclusions thus reached by reference to the bony skeleton and to the röntgen skiagraph, differentiating coxa vara, tuberculosis, septic arthritis, osteoarthritis, congenital anterior dislocation, strained ligaments and simple contusions.

The foregoing cases are diagnosed fracture of

the femoral neck. In making this diagnosis other possible conditions must be eliminated. That these are not cases of septic arthritis is evidenced by the absence of acute local symptoms and constitutional disturbance, and by the presence of shortening. The presence of shortening and eversion negative the possibility of a diagnosis of strained ligaments or simple contusion. Conditions ruled out with more difficulty are osteoarthritis, congenital anterior dislocation, coxa vara and tuberculosis. Osteoarthritis is eliminated by the absence of history of exacerbations and muscular spasm; it is true that a form of pathological coxa vara or subluxation may appear in osteoarthritis, but this is due to wearing away of the head of the bone and an upward enlargement of the acetabulum, which conditions do not exist in these cases, as evidenced by the skiagrams. Congenital anterior dislocation would be readily distinguished by the history, by manipulation, and confirmed by the skiagraph. Coxa vara may simulate fracture very closely, and possibly be combined with it. An important point of distinction in coxa vara is the diminution in the angle of the neck and shaft of the femur, with a twisting of the head backward and inward, while in simple fracture there is a normal angle with a lowering and displacement of the head of the bone. Tuberculosis remains to be considered, the absence of acute sensitiveness, muscular spasm, night cries and referred pain, together with the positive evidence of fracture from the skiagram, make the exclusion of this diagnosis possible.

In literature there are very few references to fracture of the femoral neck in childhood. In an early paper by Dr. Senn he refers to the frequency of fracture of the neck of the femur as the rarest accident during childhood and adult life, occurring between the ages of twenty-one and thirty years as one ninety-first of all fractures; between the ages of thirty and forty years as one seventy-fourth; from the ages of fifty to sixty years, one tenth, and over seventy years of age, one third of all fractures, making no mention of any cases earlier than the twenty-first year.

In a collection of two hundred and fifty cases of intra-capsular fractures reported by Sir Astley Cooper, the youngest patient was thirty-eight years of age. In the Memoirs of the Academy of Surgery, Sabatier related a case of fracture of the neck of the femur in a boy aged fifteen. Edward Stanley, F.R.S., in 1833, gives the first detailed account of a fracture of a femoral neck in a young subject aged sixteen. The patient contracted smallpox and died; examination of his hip confirmed the diagnosis. The capsule of the hip joint was entire but a little thickened, the ligamentum teres uninjured, a line of fracture extended obliquely through the neck of the femur entirely within the capsule. The neck of the femur was shortened, and there was bony union of the fragments. E. Geddings, in 1846, reported a case of fracture of the neck of the femur within the capsule in a colored boy aged eighteen, who was thrown on the ground by a companion. C. H. Hallett, University of Edinburgh, in 1847, reported the case of fracture of the femoral neck which was discovered at autopsy; woman aged twenty-three, history not known, but from her appearance and the firmness of the bone

the fracture occurred presumably a considerable period before she died. De Morgan in 1859 reported the case of fracture in the hip of a boy aged nineteen. In 1871 E. T. Barber reported a case of fracture of the femoral neck in a child seven years of age, in which a suit for malpractice followed. Testimony was largely against him, because the London *Lancet* had never reported such a case in so young a subject and because Dr. Astley Cooper did not speak of such a case in his work on fracture. The correctness of his diagnosis was upheld, and refracture proved to have occurred. C. C. F. Gay in his clinical lectures in 1878 on the fracture of the neck of the femur presents the case of a girl aged eighteen, who was suddenly disabled while standing at her work. No history of injury. The hip lesion remained unrecognized for three months, after which time manipulation overcame the deformity, and the limb was useful with only half an inch of shortening. H. Wardner, in 1879, reporting 163 cases of fracture of the femoral neck, mentioned only eight patients under twenty years of age, two of which were three years old. Cooper and Leistik report fracture in an attempt to replace dorsal dislocation of the hip in childhood, and a similar condition is reported in an attempt to reduce an anterior dislocation in a boy of six years. B. M. Cromwell in 1885 reported a case of fracture of the femoral neck in a young subject. In 1893 Dr. Royal Whitman reported from the Hospital for Ruptured and Crippled Children in New York ten cases under eight years, the youngest being two and one-half years. These he concludes were caused by falls of fifteen feet or over. Shortening of about three quarters of an inch. Probable diagnosis, fracture caused by violence which might produce fracture and because subsequent symptoms were those of fracture. Of the twenty-one cases of fracture of the neck of the femur in children in Dr. Whitman's private practice, reported in the *Annals of Surgery* for November, 1902, there are ten male and eleven female cases, of which number seventeen were under nine years and four between nine and eighteen years of age.

New Instruments.

A GLASS URETHRAL IRRIGATOR.

BY DAVID D. SCANNELL, M.D., BOSTON.

For the general practitioner the soft rubber catheter is probably without question the instrument of choice in the irrigation of the urethra in gonorrhea, where that form of treatment is carried

t. And yet its use is not entirely satisfactory, especially in large clinics, where the frequent boilings necessary to maintain the sterility of the catheters renders them in a very short time useless or nearly so as to make their employment unsatisfactory. For the general practitioner with a small genito-urinary patronage, the element of expense in such destruction is probably of little moment, but in a clinic where there is a daily average of twenty to thirty gonorrheal cases (all of which are treated), the question of expense from the consumption of catheters is not a small one.

Believing that glass tubes, if they could be shown to be safe and efficacious, would be a desirable instrument in such urethral irrigations, I experimented with various kinds in the genito-urinary department of the Boston Dispensary, where the courtesy of Drs. Arthur L. Chute and Richard F. O'Neil put sufficient material at my disposal. The tube (figured in the illustration) from which I obtained the

most satisfaction presents practically nothing new, but it is its applicability and, in some respects, its superiority that I wish to advocate.

This tube is of ordinary blown glass, 14 cm. long, 0.5 cm. in diameter (equivalent to 13 French) and slightly curved. The tip is blunt and perforated. The distal end for 5 cm. from the tip presents four perforations, each 2 mm. in diameter. The proximal end of the tube presents a small circular shoulder and a bulbous portion to facilitate attachment to rubber tubing. Experiments made with straight tubes were not satisfactory; corrugated, straight or spiral, were found not to increase the value of the tube except in price; furthermore, the addition tended to make the glass more friable. It is obvious that the material and shape of these tubes make cleanliness and sterilization by boiling simple. Repeated boilings have, of course, no deteriorating effect on the glass. In the use of a tube of this sort it is not necessary, where only irrigation of the anterior urethra is desired, to have the tube supply more than one and one half to two inches above the patient, the multiple perforations allowing a large amount of the antiseptic to escape and cleanse the urethra.

With the aid of the same lubricants that are ordinarily used with catheters, the glass-tube is introduced into the meatus and urethra with no more difficulty or discomfort than occurs with the rubber instrument; its rigidity, of course, makes gentleness in insertion a little more necessary. As a rule, unless the mucous membrane of the urethra is very much swollen, or its caliber naturally very much smaller than normal, no pain is experienced; in such cases, almost as much difficulty is experienced with the catheter. The glass tube may be introduced as far as the hilt or only far enough to cover the perforations. "Ballooning" of the anterior water passage is, of course, easily accomplished by compression of the lips of the meatus with the tube.

It will be said, perhaps, that while all these things may be true for anterior irrigation, the tube cannot be used for irrigation of the posterior urethra. So far as introduction of the tube past the cut-off muscle is concerned, this is true; but I have demonstrated repeatedly that it is only slightly more difficult to overcome this muscle after the method of Janet with this tube than with a blunt glass tube or a conical hard-rubber nozzle, aided by the usual elevation of the reservoir.

In an observation of not less than two hundred trials I have found the glass tube eminently satisfactory. Of course there are certain cases where a catheter must be used, but in the vast majority of cases it has proven of value.

To summarize the points in its favor: (1) Cheapness (a dozen such tubes costing fifty cents); (2) durability; (3) ease of sterilization; (4) cleanliness; (5) facility of use; (6) volume of ejected fluid; (7) adaptability for posterior irrigation by Janet's method.

Medical Progress.

RECENT PROGRESS IN SURGERY.

BY HERBERT L. BURRELL, M.D., AND HAYWARD W. CUSHING, M.D.,
BOSTON.

(Continued from No. 19, page 506.)

RADICAL CURE OF ANEURISM.

This surgical condition has no truly successful treatment unless it has involved a total removal of the sac, which itself may fail, should the collateral circulation be intestinal. R. Matas⁹ offers the following conclusions concerning a method of suture within the aneurismal sac and the connection between it and the main channel. He says that the favorable statistics of the last decade may be greatly increased by adoption of this method of suture—an obliteration of the sac, instead of the classical ligation of the arteries, with or without extirpation, the closure of the arterial orifice supplying the sac, whether single or multiple, by sutures, and within the sac simplified technique of the other operation. A favorable case, namely, sacular aneurism, with one orifice into the trunk, is best. It is possible by these sutures to close the lumen without narrowing the main channel. In fusiform, traumatic aneurisms, and in all with a healthy, friable sac, lost continuity of the arteries may be renewed by building a new channel and connecting the main orifices of communication. The fear that atheroma and degeneration will interfere with healing has been exaggerated, especially since it has been shown that amputations in aged patients with sclerosed arteries may well succeed. The failure and danger of the old operation of Antillius lie in the fact that ligation of the main artery, above and below the sac, will not always control the bleeding from collateral vessels opening into the aneurism, or into the main trunk between the arteries of the sac and the seat of ligation. The cutting of the sac away has the danger of interfering with collateral circulation. The operation of Antillius, more-

⁹ Med. News, March 28, 1903, p. 604; Ann. of Surg., Feb., 1903.

over, leaves the sac as an open cavity in the bottom of the wound, which heals by granulation, and induces infection, suppuration and secondary hemorrhage. All these difficulties are increased by the extirpation.

AN EXPERIMENTAL AND CLINICAL RESEARCH ON THE
TEMPORARY CLOSURE OF THE CAROTID ARTERIES,
BY G. CRILE, M.D.

Crile¹⁰ calls attention to the great danger of hemorrhage in operations on the head and neck, and to the enormous amount of time consumed in controlling the bleeding. The danger is not only immediate, but there is always, in certain cases, the fear that inspired blood will cause a late pneumonia. In order to obviate these dangers Crile practices *temporary closures of the carotid arteries*. As the result of experiments on dogs, he found that a properly adjusted clamp could be left in position, closing the artery from twenty-four to forty-eight hours, without serious injury to the arterial walls. Clotting was not observed, the circulation was re-established, and no emboli or thrombi were found in the brain postmortem. The clamp employed is so constructed that the blades are adjusted by means of a set-screw. One blade is longer than the other, and has a turned-up end in order to prevent the escape of the artery. The blades are parallel to each other when approximated, and are covered with pieces of rubber tubing. Twenty minutes previous to operations, in which pneumogastric or its superior laryngeal branch is likely to be involved, 1-100 gr. of atropin is administered hypodermically, in order to prevent inhibitory action of the heart. The carotid artery is closed with the clamp, using only sufficient pressure to approximate but not compress the walls of the artery. The control of the arterial hemorrhage is absolute except in such vessels as receive collateral supply from the vertebrae. Crile has carried out this procedure in eighteen patients during various operations on the head and neck. Both common carotids were closed in ten, one common carotid in five and one external carotid in three cases. In all there were twenty-eight closures of individual vessels. The ages of the patients ranged from seven months to sixty-nine years. There were no deaths attributable to the temporary closure of the arteries. In every instance the circulation was immediately resumed, and there were no late effects on the walls of the artery, upon the circulation in the branches or on the cerebrum. Less anesthetic was necessary with closed arteries, especially where the common carotids were occluded. In the latter case there may be embarrassed respiration. Wholly or partially releasing one or both carotids gave immediate assistance to respiration.

THE CARRYING FUNCTION OF THE ARM.

Hoffman¹¹ points out the abnormalities of the arm affecting its passive carrying function. The forearm should diverge from the upper arm at an angle of about 170 instead of a straight line, and destruction of this carrying angle may be brought about by fractures, rachitis or anything that

changes the articular surface from one facing a little outward to one facing directly downward or slightly inward. He illustrates his views with pictures, and describes his operation, in which he made a dissection of the soft parts to the humerus just above the inferior condyle, cutting three fourths through the bone and reflecting it slightly outward, making a carrying angle above the joint. He operates from the inner side to avoid involving the musculo-spiral nerve, and because it is better to bend the bone away from the cut and toward the position of correction, thus leaving unbroken the covering of the periosteum on the outer side. Simple section of the inner side will give a longer arm than a cuneiform operation on the outer.

THE BLOOD VESSELS OF THE LONG TENDONS OF THE
PALMAR SURFACE OF THE FOREARM AND HAND.

M. Tichonow¹² has published the results of an investigation of this subject, and at the conclusion of an article illustrated by two plates, the anatomical details of which cannot well be here described, formulates the following recommendations: That in case of a tendon suture it is important to note from which side the blood vessels enter the tendon and their manner of distribution in the same. In case of purulent inflammation of the synovial sheath in the carpal canal, one should not drain through openings over and under the canal, since such drainage disturbs the blood supply. Tichonow advises that one should cut through the transverse carpal ligament and preserve the vessels supplying the tendon. These rules hold also for suture of the tendons of the fingers, for the opening of abscesses in the synovial canals and in determining the vitality of the tendons.

THE RADICAL OPERATION FOR SPINA BIFIDA.

After an extensive consideration of the heretofore employed methods of therapeutical treatment of spina bifida, G. B. Schmidt discusses at length the radical operations and their results. From a compilation of the statistics of the clinics of v. Bergmann and König, it is shown that only 18% of the cases remained permanently cured. He then describes the method of operating which he himself, up to the present time, has used only in three cases with good results. The stages of the operation briefly consist of the dissection or exposure of the sac, the involution of the sac and closure of the bony opening, the closure of the skin incision. For the exact details of the operation the original article¹³ must be consulted. The essentials of his method are: (a) the possibility of infection of the meninges, to which children are especially susceptible, is reduced to a minimum; (b) the formation of a fistula is excluded; (c) the provision for the nerves, (the freeing and reposition, or even resection of which, if the point of origin is below the sacral plexus, is not without danger) is towards their preservation; (d) the definite closure with the involutioned sac, which is fixed in the bony defect as an organic tampon, up to the present time has shown good results, and after an extended period has permitted no recurrence.

THE UNRELIABILITY OF MICROSCOPIC DIAGNOSIS OF MALIGNANT DISEASE.

C. H. Whitford¹⁴ has observed in numerous instances that the histological diagnosis of cancer sarcoma, or inflammatory tumors, has failed to correspond to the subsequent course of the disease. He claims that the experiences of other writers show that the microscope fails to distinguish the earlier stages of malignant tumors from inflammatory nerve growths. He places more weight, in cases where the macroscopic and microscopic conditions contradict one another, on the clinical condition of the patient, and the macroscopic appearance of a fresh section, than on the microscopic diagnosis.

PERITONEAL ABSORPTION.

Some interesting experimentation relating to the power of absorption of fluids by the peritoneum has been made by Klapp¹⁵. Solutions of milk sugar were used in dogs, and the amount of absorption was determined by the analysis of the urine for sugar.

First the power of absorption of the peritoneum was compared with that of the subcutaneous tissues. The conclusions were that the excess of power of absorption of the peritoneum depended wholly on its large area of surface. It was found when the sugar solution was injected, not in one but a large number of different places, so that a large area of subcutaneous tissue was called upon to absorb it, that the capacity for absorption nearly equaled that of the peritoneum. Next the principal lymph trunks of the peritoneum—the ductus thoracicus and the ductus lymphaticus dextra—were ligated without diminishing the peritoneal power of absorption, which fact Klapp concludes shows that the absorption is through the blood vessels and not dependent on the lymphatic system. He also claims to have observed that heat increases to a slight degree the power of absorption of the peritoneum, but that cold diminishes it to a much greater degree. Finally, that evisceration through a long abdominal incision, for different periods of time, shows that if the exposure does not exceed one quarter of an hour, absorption is increased apparently from the resulting arterial hyperemia. With exposure exceeding this period, the power of absorption diminishes.

HEMORRHAGE INTO THE OMENTAL BURSA.

K. Grassman¹⁶ observed a peculiar case of hemorrhage into the omental bursa, feigning symptoms of acute intestinal obstruction. The patient, a perfectly healthy man, was seized suddenly with collapse after a meal, and the bowels could not be made to move after a number of enemata. Laparotomy was performed, with cocaine anesthesia, and the entire peritoneum was found filled with blood, which seemed to come from the lesser omental pouch. On autopsy it was discovered that an adenomatous growth in the Spigelian lobe had ruptured the liver, and thus given rise to the bleeding. The case illustrates well the difficulty, and even the

impossibility sometimes, of making a correct diagnosis in abdominal conditions.

RADICAL OPERATION OF CONGENITAL HERNIA IN INFANTS.

Karewski¹⁷ has recently claimed that he has obtained satisfactory permanent results by operating as follows: After the usual division of the superjacent layers he isolates the hernial sac without opening it if possible. When free he closes it at its peritoneal attachment with a "purse-string" suture. This is a sufficient closure even when the patient coughs violently or with large inguinal rings. Suture of the "pillars,"—transplantation of the cord,—the Bassini method and other radical methods in children up to four years of age are shown to be superfluous.

He reports some cases without recurrence at the end of six, ten and twelve years. The operation by this method is much more rapidly done than by the usual ones. The wounds heal well even when the patients have had little post-operation cleanliness, a condition difficult in such young patients as Karewski reports, namely, in infants in the first months of life.

ETIOLOGY OF POST-OPERATIVE VENTRAL HERNIE.

Dr. Oscar Wolff¹⁸ after a careful investigation of the different methods of uniting operative abdominal wounds, the different suture materials, the after treatments in the form of various kinds of bandages or supports, concludes that one must accept that it is immaterial how the abdominal wound is united or what suture material is used; that the reason for the production of a hernia (post-operative) must be sought elsewhere. He noted that the only apparent common factor in these cases was that when a hernia was found a careful record usually showed that during the first few days following operation distention due to tympanitis had been present. This caused tension on the sutures—the fascial being more unyielding gave way before those in the more elastic skin. The skin remains united; the deeper layers yield. This occurs when, for any reason, the abdomen is distended. He therefore considers it of great importance to create conditions by which meteorismus will be avoided, claiming that meteorismus and hernia stand in relation to each other of cause and effect.

With this idea in view, Wolff, for a period of two years, has only completely sutured those wounds in which he was reasonably sure of an uneventful convalescence. In all cases when more or less abundant secretion was expected, as from the wounded surface of an inflamed peritoneum, the wound was drained by a small iodoform gauze wick through an interval between the sutures. In this way he claims the distention of the abdomen from inflation of the intestines is less. Since using this method more extensively, that is, since he has prevented meteorismus he has become convinced that the abdominal suture holds firmer, is more permanent, and hernia are of less frequent occurrence. The duration of wound repair is only slightly more prolonged, a disadvantage more than counterbalanced

by the non-occurrence of a ventral hernia. The view of Wolff in regard to tension from meteorismus, or in fact intraabdominal tension from any cause, as a reason for subcutaneous separation of an abdominal wound, seems plausible; but one fails to see how wound drainage would control the distention of an intestine by gas formation.

RADICAL CURE OF INGUINAL HERNIA.

S. Goldener¹⁹ reports the results of his study of eight hundred patients treated during the five years preceding 1899 by the Bassini operation for inguinal hernia at the Albert Klinik in Vienna for the purpose of learning the end results. No case was considered in which the post-operative period was less than two years or the patient had not resumed his active life. He counted as a recurrence a case when the patient showed a protrusion at the external inguinal ring; when a distinct defect existed in the muscle scar, and also if a femoral hernia had developed on the operated side. The result showed 7.5 % of recurrences. It occurred most frequently in the so-called "lower angle" of the wound where there was the greatest tension from the sutures, next in the abdominal wall in the scar, finally, when the suture of the muscles to Poupart's ligament failed. The technique of a second operation in these recurrent cases should be limited to the closure of these defects without again extensively exposing the cord and splitting the posterior wall of the inguinal canal. In children only one recurrence was noted in fifty-eight cases. An operation is not recommended earlier than the fifth year of age, unless the hernia is marked, since cure without operation has been obtained. Contraindication to operation are old age, organic disease of the heart, lungs or kidneys, diabetes, infants. With ventral hernia in patients over forty years it is recommended to avoid operation.

There were three deaths—one from narcosis, two from pulmonary emboli. Suppuration during wound healing often occurred, but it is considered that the condition of the muscles and the age of the patient are more important factors as regards a radical cure than failure of the operation wound to heal by primary union.

This report is interesting in that it furnishes the more recent results from the method of the Bassini.

THE LOCALIZATION OF GASTRIC TUMORS.

The following point in establishing the diagnosis of gastric tumors is noted by Glaessner²⁰. It is based on the presumption, which the writer claims to have established as a fact, that the fundus of the stomach is an area in which pepsin and "labferment" is produced while only pepsin is secreted in the pyloric portion. He was able by investigation with the "test breakfast" of the stomach contents to determine the site of the tumor in many cases when the diagnosis was subsequently confirmed by operation or autopsy. When the "labferment" and pepsin were equally diminished, the tumor was in the fundus, but when the "labferment" in contradistinction to the pepsin is retained a pyloric growth existed. Hence, not only for diagnosis but also for operative

treatment, the possibility of determining the site of a neoplasm from chemical investigation of the gastric contents assumes greater significance, especially when other diagnostic characteristics of gastric tumors are wanting.

SECTION ON PRACTICE OF MEDICINE.

W. S. THAYER, M.D., OF BALTIMORE, CHAIRMAN.

(Concluded from No. 20, page 537.)

THIRD DAY. THURSDAY, MAY 7.

COMBINED MEETING WITH THE SECTION ON HYGIENE AND SANITARY SCIENCE.

SYMPOSIUM ON TYPHOID FEVER.

ON THE SOURCES AND MANNER OF INFECTION OF TYPHOID FEVER.

DR. WILLIAM H. WELCH of Baltimore said that there was no missing link in the chain of proof that the typhoid bacillus was the cause of typhoid fever. At present there was no positive or experimental proof that the origin of the disease could be through the respiratory tract; it could only arise from the injection of the typhoid bacillus into the alimentary canal. The bacillus was eliminated from the body through feces and the urine, and in very rare instances it might be found in the sputum, but this was so rare as not to deserve consideration. He emphasized the importance of the knowledge of the bacillus being found in the urine of typhoid patients, even for a long time after convalescence had become established. This fact was a very important one from a prophylactic consideration. Another important factor in the causation of typhoid fever was the dosage. The source of the infection was *the typhoid patient*. If one could prevent the typhoid bacillus from gaining an exit from the typhoid patient he believed that typhoid could be made to disappear from the world. He referred to the experimental work of Reed, Vaughan, Shakespeare and others, in which it was shown that the majority of the cases were not attributable to drinking water but to a direct transmission from one typhoid fever patient to another; in the cases of the soldiers the disease was transmitted by things about the tents,—articles of bedding, etc.,—and they brought out the agency of flies and other insects in the transportation of the disease. The bacillus could be transmitted in various ways, but he believed that in many communities the solution of the prevention was likely to be found in the powdered filtration or sand filtration. He thought we were far behind the Continental countries in this respect. Typhoid fever was occasionally traced through the ingestion of vegetables or raw foods; also through the dust in the air. He also took up the consideration of the contamination of milk occurring chiefly through the air or through the water used in washing out the cans. Milk he said was an excellent medium for the growth of the bacillus. Milk had been the cause of many epidemics.

SOME UNCONSIDERED HINDRANCES IN THE PROPHYLAXIS OF TYPHOID FEVER.

DR. JOHN S. FULTON of Baltimore read this paper, and said that our knowledge of typhoid fever includes all the facts essential to successful prophylaxis. Notwithstanding the fullness of our information and the efficiency of our means, the prophylaxis of the disease is a somewhat conspicuous failure; for typhoid fever is the commonest of the continued fevers of the United States. This failure may be in great part explained by three considerations.

First. The great majority of cases of typhoid are not recognized either *intra vitam* or *postmortem*. The cases which escape diagnosis are (a) of ambulant and very mild cases, a great majority; (b) of cases at the extremes of life, a majority; (c) of anomalous cases, a majority; (d) of plain, uncomplicated bed-ridden cases, about 40 %. This defect of diagnosis, shared by physicians in all parts of the country, and amounting to nearly 50 % of observed cases, is chargeable, primarily, to (e) a serious default of American medical education; and after that to (f) a delusion, from which no part of the country is exempt, that malaria is a considerable cause of mortality in the United States.

Second. The view that typhoid fever is a distinctly urban disease is erroneous. If the cities of this country be classified upon a descending scale of population, it will be found that the typhoid mortality rises as populations diminish, and that the incidence of typhoid upon rural populations yields the highest mortality observed in the country. Typhoid fever is distinctly a rural disease.

Third. The general prophylaxis of typhoid in cities, though measurably successful so far as cities are concerned, cannot by its widest conceivable extension materially affect the typhoid mortality of the whole country, nor can it yield perfectly satisfactory results in cities; for this general prophylaxis is concerned with but the least part, and has not immediate relation with this least part of the total morbidity from typhoid fever.

The greatest prime factor in the dissemination of typhoid fever is its occurrence in small communities and rural districts where the customary disposal of human excrement admits its distribution by wind, water, animals and insects. The prophylaxis of typhoid is essentially a defense against excremental contamination. Its special hygiene must include, besides the care of food and water supplies, the screening of privies against flies, exclusion of flies and other insects from, and their destruction in, dwellings and places where food and drink are stored.

The isolation of typhoid fever cases will separate the remainder of the household from unnecessary contact with the sick or his belongings, and will prevent the access of flies and other insects to the patient or his excreta.

Disinfection in typhoid fever will include the person and clothing of the patient, the hands of the attendant, and the immediate disinfection of excreta as soon as passed. For the immediate disinfection of excreta the addition of an equal bulk of quicklime is recommended. We have not at present a method of disinfecting excreta which meets all the practical requirements of speed, certainty and cheapness.

Success in the prevention of typhoid depends, first, upon prompt diagnosis of the disease, and, next, upon the effectiveness of defenses maintained in the immediate environment of each case.

DR. JOHN H. MUSSER of Philadelphia thought that, with the more modern means for making diagnoses, an earlier diagnosis should be had. He advised the use of urotropin as a means of lessening the number of bacilli contained in the urine of these patients. This drug would also tend to prevent one of the complications of typhoid, that is, cystitis.

DR. DELANCEY ROCHESTER of Buffalo, N. Y., advised the use of large amounts of chloride of lime for disinfecting the stools.

DR. JAMES J. WALSH of New York referred to a large city in this country where, for ten years, the introduction of a filtration plant had been held back because of political reasons. Three thousand deaths occurred, and yet nothing was done toward punishing any one for criminal negligence.

THE MODE OF TRANSMISSION OF YELLOW FEVER.

DR. JAMES CARROLL, U. S. A., opened the discussion of this topic. He discussed some of the older theories and the lessons learned in the past from observation and experience alone. The more modern theory was based on the supposed bacteriologic origin of the disease. Finley's theory of the transmission of the disease by means of the mosquito was considered. He claimed that yellow fever could be produced by the mosquito only. Disinfection and fumigation was a perfectly useless expediency, entailing a useless expense of time and money.

DR. STAMFORD E. CAILLÉ referred to certain notable investigations made by Reed, Carroll, Agramonte and others, which had contributed four sets of precious facts: (1) Fresh blood or its serum taken from a case of yellow fever, during the first days of the attack, would give the disease if hypodermatically injected into a non-immune. Hence the blood contained the poison. (2) The female *stegomyia fasciata* mosquito, serving as an intermediate host, could convey the poison to non-immunes. (3) Excluding all mosquitoes, fomites prepared and kept under all the known conditions universally known to be the very best for supplying the most virulent fomites, failed to infect seven non-immunes extraordinarily exposed to said fomites. (4) Disregarding filth and fomites, because two years' warfare against them had proved ineffectual, and limiting sanitary measures solely to excluding imported cases, to isolating every home case, and preventing in every possible way the access of mosquitoes, these measures were followed in Havana by the total disappearance of all home cases, from Sept. 28, 1901, to May, 1903. He said that the case of fomites *versus* *stegomyia* was of the utmost importance for prevention and commerce, and deserved consideration. The only advocates of fomites known to him who had published their views were two distinguished sanitary officers, Punnett of Mississippi and Sonchon of Louisiana. He then took up the arguments of both to prove that the *stegomyia* was not the sole cause, but that fomites were also a cause. He said that Carter, writing in favor of the *stegomyia*, claimed that every disease having an intermediate host was

propagated solely by its special host and never by fomites. He doubted whether we could be justified at present to accept this as a final conclusion. Dr. Caillé, so soon as he was convinced that mosquitoes followed routes of travel, and that the stegomyia was a conveyer of yellow fever, embraced the stegomyia as a welcome substitute for fomites. In fact he had never secured satisfactory evidence of the proof of a single case either of direct contagion or of infection by fomites. He concluded his paper as follows: The probabilities now are that the stegomyia, the only cause yet proven, was the sole cause for the dissemination of yellow fever; time was required to convert these probabilities into certainty. Boards of health, should they neglect any practical measure of warfare against the stegomyia, would deserve the severest punishment of the worst criminals. Southern boards of health were excusable for over-precaution against yellow fever. States adjacent to Louisiana had power, by sanitary restrictions, to strangle the commerce of New Orleans, and Louisiana should not abandon the disinfection of fomites until approved by said states. Boards of health were representatives of the people, and were justifiable in continuing to disinfect fomites as long as public opinion favored this measure, and until the probability of its inutility was converted into certainty.

DR. EDMUND SOUCHON, president of the Louisiana State Board of Health, continued the discussion. He said the foremost perplexity of the responsible officers was the question of the treatment of fomites; from the known experiments of Reed, Carroll, Guiteras and Ross it was contended that the disinfection of fomites was unnecessary. To these experiments the responsible officers oppose the fact that they were made at a time of the year when yellow fever was not at its worst, except, perhaps, the early experiments of Ross. Again it should be considered that 30% of the non-immunes bitten by infected mosquitoes did not develop yellow fever. He thought, therefore, it was unreasonable to expect that all experiments made with fomites should develop yellow fever. The responsible officers do not contend that fomites transmit yellow fever; they modestly state that they do not know. He said that for the present, and until further progress, the responsible officers were unwilling to make any change in the quarantine regulations against yellow fever.

DR. C. W. STILES of Washington said there were certain biological facts in the consideration of yellow fever. The cause of the disease belonged to one of three different groups: (1) bacterium, (2) flagelia and (3) sporozoa. The entire history of the disease, with its short incubation period, etc., shows that the organism was probably reproduced by nonsexual methods. The bacterium seemed to be excluded by the history of incubation in the mosquito. Regarding the flagelia nothing was known regarding its sexual development. He thought the parasite which was the cause of the disease possibly was a sporozoa.

SOURCES AND MANNER OF INFECTION OF PLAGUE.

DR. W. J. CALVERT of St. Louis, Mo., read this paper, giving a historical sketch with reference to

great pandemics, more especially to the present. He considered the features of the bacillus pestis, its viability and possible modes of dissemination, and portals of entry into the human system. He said that no matter if it was stamped out in this country, it would be likely to reappear so long as such places as Canton and Hong Kong existed.

PROPHYLAXIS OF PLAGUE.

DR. J. J. KINYOUN of Philadelphia said that the *sine qua non* was the accurate diagnosis of the first case, and that the clinical forms were so varied that error in diagnosis of first cases was the rule. Plague might resemble anthrax, tonsillitis, mumps, diphtheria, erysipelas, pneumonia, acute pleurisy, malignant pericarditis, endocarditis, typhoid, typhus, relapsing and malarial fevers, acute dysentery, miliary tubercle, septicemia, pyemia and syphilis. These forms of plague and its insidiousness, and the inexperience of the profession, rendered plague one of the most difficult to recognize. For diagnosis a bacteriological examination was essential. He then considered the measures to be adopted in caring for such patients, dividing up the treatment into the following different heads: (1) Isolation pending a diagnosis; (2) segregation under medical supervision of contacts and suspects; (3) disinfection of premises; (4) sanitary measures in immediate vicinity; (5) destruction of vermin and their examination; (6) general measures against the dissemination of the disease. He then referred briefly to the consideration of maritime commerce, the personnel of vessels, the cargo, the vessel itself. Under the heading of maritime quarantine, he considered the measures to be taken in a port where plague existed, both in its detection and eradication, and the measures to be taken to prevent its spread.

DR. F. G. NOVY of Ann Arbor, Mich., continued the discussion. He said that in plague we had a well-defined disease caused by a well-defined organism. The organism can be readily seen and recognized under the microscope in every case brought to the postmortem table. The experiments can be made to demonstrate the disease in animals to any one, and the organism complies with every requirement. The question came up, Will this organism always produce the disease? He emphasized the fact that plague was essentially a disease of animals and primarily was not a human disease. The disease was transmitted by the bites of animals, such as the rats or rodents of China. How the disease was communicated to man, what was the portal of entry, was a very difficult question to answer, and possibly never would be answered satisfactorily. The virulency of the germ decreased the longer it was kept in artificial culture. The organism he did not consider to be very resistant, and could be easily destroyed. Besides isolation of the sick, disinfection, segregation, etc., he said we have a powerful method of controlling the disease; that is, with the serum.

ARTHRITIS DEFORMANS.

DR. THOMAS MCCRAE of Baltimore read this paper, reporting a study of a series of 110 cases from the Johns Hopkins Hospital. Reference was

made to the obscurity of the pathology and our ignorance regarding the disease. The two great types of the disease were mentioned and the distinction between them. Certain cases of this series apparently showed the co-existence of these two different grades. The whole series showed an equal number in the two sexes, but a striking small number among the colored, only 4 out of 100, a proportion of 26 white to 1 colored. The native born were 96. There was an absence of a history of exposure to cold or wet. There was a family history of arthritis in 44. For clinical study the cases were divided into four groups: (1) Heberden's nodes; (2) the polyarticular form; (3) the mono-articular form; (4) spondylitis. Of the first group no cases are in this series unless the joints were involved. Of these there were 9, but in only 2 of these were the manifestations severe. The poly-articular forms were the largest group, 94, including 2 cases of "Still's disease." In half of these the onset was before the age of thirty. Special stress was laid on the acute character of many of these. In 41 the onset was sudden. Two main classes of cases can be recognized—a slow, progressive type and one in which there were repeated acute attacks. There were 30 cases in this latter group. Such cases were nearly always mistaken for acute articular rheumatism. The distinguishing features of these cases were dwelt upon, and the importance of other infections, such as influenza, in bringing on attacks. The usual high pulse-rate and the temperature curve were noted. Especial stress was laid on the importance of the study of the early cases, if we are to clear up the disease. The diagnosis and treatment were also discussed. Of the mono-articular form there were 3 cases. Their doubtful character was discussed. The fourth group, spondylitis, comprised 22 cases, 13 of spinal involvement only and 9 with other joints in addition. In 15 the whole spine and in 7 only a portion were involved. The work of Dr. Goldthwait of Boston was noted in this group. The importance of knowing the features of the local involvement was emphasized, and the points in the diagnosis and treatment.

ALBUMINURIA IN DIABETES MELLITUS. ITS IMPORTANCE AS A FACTOR IN THE CAUSATION OF COMA.

DR. ARTHUR R. ELLIOTT of Chicago read this paper, and said that the following conclusions seemed to be warrantable: (1) Albuminuria was a frequent occurrence during the progress of diabetes, over one third of all cases manifesting this symptom at some time during their course. (2) Albuminuria in diabetes may for clinical purposes be divided into two varieties, toxic and degenerative. (3) Toxic albuminuria was generally of acute onset, arising during the later stages of the severe form of the disease, as the result of irritation of the tubular epithelium, producing hyaline degeneration thereof, and due to the presence of acid toxins in the blood and urine. (4) Toxic albuminuria was an invariable precedent and accompaniment of coma, and may be regarded as of the greatest prognostic significance. (5) Toxic albuminuria and its associated renal changes were the final determining cause of coma diabeticum, by producing a

heaping up of sugar and toxins in the blood, through diminished permeability of the renal secreting structure. (6) Degenerative albuminuria occurs with great frequency during the progress of the mild type of the disease, and was of renal origin and produced by a gradually developing nephritis, which arose from prolonged hyper-function and impairment of renal nutrition. (7) The appearance of albumin under the circumstances, while of little immediate significance, was of the greatest eventual importance, as indicating the intrusion of chronic nephritis into the already manifold clinical difficulties. (8) A few cases of albuminuria in diabetes may be produced by venous stasis due to cardiac asthenia, and under such circumstances will be associated with other evidence of heart failure. (9) Albuminuria in diabetes was never devoid of importance. It may be of the greatest significance, and was always of sufficient import to receive the earnest attention of the clinician.

FOURTH DAY: FRIDAY, MAY 8.

THE PASSING OF CHRONIC RHEUMATISM.

DR. JAMES J. WALSH of New York read this paper. He said there were four different conditions, which were often called chronic rheumatism, but without any good reason. The most common form of pseudo-rheumatism was the relaxation of joints which occur in the ankle and which was known as flat-foot, or which followed the dislocation of joints producing tissue changes which made the patients very susceptible for all their after life to changes in the weather. Just as there were relaxations of the ankle joint, so could there be relaxations of other joints. A second form occurred in the so-called occupation neuroses. A third form of vague pains often attributed to rheumatism was neuritis. Persons who were exposed to the weather, and who used one set of muscles more than another, especially if there was an absorption into the system of such toxic substances as lead and alcohol, were especially prone to a neuritis in the nerves supplying the overworked muscles. Again, a certain number of cases of so-called chronic rheumatism in this country presenting evidences of joint degeneration following acute attacks of arthritis were undoubtedly not genuinely rheumatic in character, but were of gouty nature. He said that according to recent statistics gout was only three fourths as frequent in this country as in England. Acute gout was very difficult to differentiate from acute rheumatism. After considering briefly three forms of rheumatoid arthritis, he stated that it was easy to understand that but little space was left for the so-called chronic rheumatism. Certainly, cases of true chronic rheumatism with progressive pathological changes in joint tissues, for which no other cause except rheumatism could be found, were very rare, and he confessed that he had never seen such a case.

HEMOGLOBINURIC FEVER: ITS CAUSES AND TREATMENT.

* DR. WALTER SHROPSHIRE of Yoakum, Texas: A report of 202 cases collected showed 61 treated without methylene blue, or with less quinine than 15

gr. per diem, of which 26.2% died and 73.8% recovered; while 112 cases treated with 20 gr. or over of quinine, 16.9% died and 83.1% recovered. Four were treated with methylene blue, with one death and three recoveries. It was shown that quinine not only lowered the death-rate, but also lowered the percentage of recurring paroxysms. The following facts were presented: (1) That this disease always occurred in persons suffering repeated attacks of malaria; (2) that it nearly always followed one or more paroxysms of malaria at the proper time for its next exacerbation; (3) it had all the characteristics of malaria, chill, fever and sweat; (4) that where adequate examination of the blood was made the hematozoa of malaria were found; (5) its habitat, that of the most violently malarious districts. After a review of the effects of quinine it was indeed difficult, if not impossible, to conclude logically that it could produce hemoglobinuria. Summing up the evidence for and against quinine as a cause of this disease, he said that 29.4% physicians affirmed and 70.59% denied it. When quinine was suspended, 73.8% recovered; when quinine was administered 83.1% recovered. Distinct recurrences of attacks after the first appearance of blackwater in non-cinchonized patients, 9.8%; distinct recurrences of attacks after the first appearance of blackwater in cinchonized patients, 4.4%; per cent of cases occurring from quinine alone, 0%; per cent of cases occurring from malaria without quinine, 15%; per cent of cases where quinine was supposed to aggravate, 5.9%; per cent of cases where quinine was thought not to aggravate, 55.41%. This gave a preponderating evidence against quinine as a causative factor in the production of this disease. In the treatment of this condition he advised giving 40 gr. of quinine per diem, either intravenously or hypodermatically, until the next period of an exacerbation was safely passed; then it should be discontinued for three or four days, and then repeated in 20 to 30 gr. doses every four to six days, until five or six weeks have passed without a paroxysm. Attention to liver and bowels was emphasized, with the ingestion of large doses of very hot water.

SOME CLINICAL ASPECTS OF TUBERCULAR PERITONITIS.

DR. JOSEPH EICHBERG of Cincinnati read this paper, and said that among the many startling results that have followed the introduction of laparotomy, exploratory and curative, none showed a more decided departure from beliefs of a former generation than the present attitude of the profession with regard to tubercular peritonitis. On the basis of postmortem findings various classifications had been made, but the simplest was the dry and the exudative, included under the latter head the caseous and purulent varieties. From a clinical standpoint Hawkins divided them into four varieties, as follows: (1) Latent; (2) severe, with ascites and a spontaneous tendency to remissions or encapsulations; (3) cheesy-purulent form, with frequent formation of large caseous masses and adhesions; (4) fibro-adhesive form. He said there was much difficulty in establishing any basis of classification, either pathological or clinical.

Laparotomy did not always establish a diagnosis. Good results have followed simple incision, irrigation of the cavity, drying of the peritoneum, resection of diseased parts and other modifications. The essential feature seemed to be incision. He stated that the percentage of recoveries without operation, for all ages, with or without complications, was greater than with operation. In five and a half years Herringham observed 25 cases diagnosed as tubercular peritonitis, of which 19 recovered without operation and 3 were improved. He found the only justification for operation was a return and increase of the ascites, after puncture. Hawkins reported 59 cases which recovered, all but 3 being treated by internal medication. Czerny cautioned against expecting too much from the operation. He believed that the opinion that a diagnosis of tubercular peritonitis called for an immediate laparotomy was erroneous, not to say vicious.

TUBERCULOSIS IN THE NEGRO.

DR. SEALE HARRIS of Union Springs, Ala., said that tuberculosis was unknown among the native Africans until the infection was carried to them by slave traders and colonists. It was a rare disease among the slaves in the Southern States, because the hygienic methods of living enforced among slaves prevented their becoming infected. Statistics showed an increase of tuberculosis among the negroes during the past forty years. Then followed statistics for Southern States and for his home in Alabama. Among the causes he gave for increase of tuberculosis among the negroes, comparing them with the white population, were the small lungs, less lung capacity and less chest expansion. The filthy habit of spitting was one of the great causes of the dissemination of the disease. Syphilis was a very great predisposing factor in tuberculosis, and the increase in syphilis in the past thirty years had been *pari passu* with that of tuberculosis. He then considered the methods to pursue in limiting an infectious disease like tuberculosis, such as increasing the strength and vitality of the individuals of the race, thereby rendering their tissues an unsuitable soil for the invasion and propagation of the specific germs of the disease, and in preventing his exposure to the infecting agent, as by the isolation of those already infected and by destroying the organisms causing the disease.

SHOULD THE TUBERCULOUS PATIENT KNOW THE TRUTH REGARDING HIS CONDITION.

DR. C. P. AMBLER, of Asheville, N. C., read this paper. He believed it to be the duty of the physician to explain to the patient the dangers to himself and to others; to point out where he was most apt to make mistakes; to give explicit directions regarding his hygienic life, including diet, exercise, work, physical or mental application, secretion and excretion, sexual relations, and in fact to go fully into the whole question of the hygiene of life. Such instructions should apply to the incipient as well as the advanced cases. To get the co-operation of the incipient cases they must know the truth. The laws of health demand that the patient fully realizes the danger to himself and others. The patient should be appealed to that it was un-

kind to his friends not to make every effort to protect them. The education of the public, and the careful education of the patient as regards infection of others, would accomplish more than legislation. In the fight against the spread of tuberculosis the patient should, first of all, know the truth regarding his condition.

Officers elected: For chairman, Dr. Alexander Lambert of New York; for secretary, Dr. J. S. Miller of Chicago; for member of House of Delegates, Dr. Frank A. Jones of Tennessee.

AMERICAN MEDICAL ASSOCIATION.

PROCEEDINGS OF THE FIFTY-FOURTH ANNUAL MEETING, HELD IN NEW ORLEANS, LA., MAY 5, 6, 7, AND 8, 1903.

HOUSE OF DELEGATES, MAY 5.

THE House of Delegates met in the Council Chamber of the City Hall, under the Presidency of Dr. FRANK BILLINGS of Chicago, Ill.

Dr. HENRY D. HOLTON of Vermont presented the report of the

COMMITTEE ON PROPHYLAXIS OF VENEREAL DISEASES.

The committee recommended holding a National Congress for the Prophylaxis of Venereal Diseases under the auspices of the association. The committee believes that this will mark an epoch in the history of this great national body of medical men.

The committee submitted the following points to serve as a basis for such a congress:

(1) As the states cannot with impunity ignore the existence of venereal diseases, and as it is the duty of the state to protect the people from the ravages of contagious diseases, there should be instituted through the state and district societies a propaganda of action in each state or district society looking towards a proper recognition of venereal diseases by the different legislatures.

(2) That the American Medical Association authorizes accredited delegates from each state, or by appointing special committees for this purpose, to organize such a movement in their respective state and district societies, and to send delegates to such a congress.

(3) That such delegates may then, fortified by the authority of the American Medical Association, in such a congress convened, bring to bear on their home legislatures the necessity of legislation against the spread of venereal diseases.

(4) To appoint a central committee of organization to be in touch with the various state committees. The congress would discuss and act on the following questions:

Prostitution.—Its causes and how to diminish its extent: (a) Safe-guarding minors; (b) by raising the age of consent; (c) socio-economic measures; (d) educational measures; (e) creation of a provident education law.

Prophylaxis by treatment.—(a) Making venereal diseases reportable, without giving names and addresses, solely for statistics of morbidity; (b)

liberal and enlarged hospital and dispensary facilities, with gratuitous treatment.

Legislation.—(a) State laws against diffusing syphilis and venereal diseases in an extra-genital way; (b) certifying the health of wet nurses; (c) regulating the profession of ritual circumcision by barbers, by dentists; (d) trade sanitary laws against transmission of syphilis.

Individual prophylaxis.—(a) By teaching the avoidance of dangerous contact; (b) by instructing the diseased how to avoid infecting others.

The committee recommended that the name of the congress be the NATIONAL CONGRESS FOR THE PROPHYLAXIS OF VENEREAL DISEASES, under the auspices of the AMERICAN MEDICAL ASSOCIATION.

On motion the report of this committee was referred to the Business Committee, with instructions to make a report before the house, with recommendations.

SECRETARY SIMMONS read the report of the

COMMITTEE ON SCIENTIFIC RESEARCH.

Early in the fall this committee advertised in the pages of the JOURNAL, and through other medical journals, that five grants of one hundred dollars each would be made to persons applying for the same who could show sufficient training and opportunity to warrant the making of a grant. Applications were received from a number of physicians. From these the committee have selected as most deserving the following:

Dr. Newton Evans and Dr. F. J. Otis, Battle Creek, Mich., for work on systematic infection with blastomycetes; Mr. G. F. Ruediger, Rush Medical College, Chicago, for work on virulent streptococcus; Dr. J. T. Moore, Galveston, Tex., for a study on the latency and relapses of malarial fever; Dr. H. E. Wetherell, Philadelphia, for an experimental and clinical study of sweat secretion.

On motion this report was referred to the Board of Trustees. The board subsequently reported in favor of appropriating the money when a report has been made and accepted by the association, said report to be the property of the association. This report was adopted by the House of Delegates.

Dr. T. J. Happel, Tennessee, president of the Board of Trustees, presented the annual report of the board for the year 1902. The report showed the great growth made financially by the association in the short period of five years. At the Denver meeting the treasurer reported total cash received from members for the year, \$32,200; receipts for 1902, from the same sources, \$59,180, showing a gain of \$26,980, indicating but little short of twice as many members. The total amount of cash in the treasurer's hands was \$17,092.85, which included that reserved for building purposes, \$3,000. The tables show cash on hand \$21,590.67, being a gain in cash of \$1,497.82; and a building on which the association has spent \$74,516.96, a gain of \$71,546.96 over the reserve funds. The total Journal business, including cash in hand, as shown by the report of the trustees for 1898, was \$17,140.97. This year (1903) the books of the Journal office show in cash \$130,021.30, which amount includes \$9,000 less in depositions, but not considering that the face of the books show a gain of \$82,891.23 in business over 1898, the gain

being almost double the total business reported that year. The business for this year shows a net profit of \$40,140.56.

The board discussed the matter of national incorporation, and a summary of the conclusions reached, with reasons as to each proposition, is as follows:

(1) The amendments to the articles of incorporation and the by-laws, adopted at the Saratoga meeting, and ratified at the meeting in Chicago in 1902, are legal. The requirements above referred to—that they should have been proposed in open meeting one year previous to being acted on and published—had no binding validity, because the American Medical Association is a corporation of the state of Illinois.

(2) As to the propriety of so small a number constituting a quorum at an adjourned session, that is a matter which the association must decide for itself. There is nothing in the by-laws to prevent any number, even to the full membership of the association, attending the adjourned session, if they so desire.

(3) The board decided that it was not its duty to take steps towards securing the proposed national incorporation.

The report of the board was referred to the Business Committee. The Business Committee recommended the adoption of the report of the Board of Trustees, and, in common with the board, the committee regretted the difficulty connected with national incorporation. The committee felt that no further action on this subject, namely, national incorporation, should be taken at this meeting.

It was moved that the report of the Business Committee on the report of the Board of Trustees be adopted, with the exception of that part pertaining to national incorporation, and that a committee of five (5) be appointed to secure the advice of the best legal talent in the United States, as to whether the association could be incorporated or not under a national charter, said committee to report at the next annual meeting to the House of Delegates. [Carried.]

DR. E. ELIOT HARRIS, New York, presented the report of the Committee on the Establishment of a National Bureau of Medicines and Foods.

The report was received, and the committee continued.

Dr. Harris also presented the report of the Committee on Revision of Code of Ethics, and at the conclusion of the report, he offered a resolution that the Special Committee on Revision of the Code of Medical Ethics unanimously recommend that its report be referred to an enlarged committee, consisting of this Special Committee, and one delegate from each state not already represented on the Special Committee, to be appointed by the president. He moved, further, that the report of the committee and its resolutions, and any amendments pertaining to this subject, be referred to the Business Committee for action.

DR. CHARLES A. L. REED of Ohio offered a substitute for the report of the committee, also a new Code of Ethics.

The substitute report, together with the resolutions offered, and the report of the Special Committee, were referred to the Business Committee.

DR. L. S. McMURTRY, Kentucky, presented a

report of the Committee on Association Medal. He asked that the committee be empowered to go forward and arrange specifications and details, so as to be able at the next meeting to present material that would be worthy of the award of the medal. This power was granted the committee.

The Committee on Senn Medal reported that it had carefully considered all of the papers presented, but that no paper had met the requirements, therefore the medal was not awarded to any one. The report was accepted.

DR. HENRY D. HOLTON of Vermont presented the report of the Committee on Rush Monument Fund.

The committee asked that a sum not exceeding \$500.00 be placed to its credit, to defray expenses incidental to the unveiling of the monument, any portion of this sum not being expended to be returned to the treasury of the association.

The report showed that the committee had already collected \$15,036.35.

On motion the report was accepted and referred to the Board of Trustees, with the recommendation that money be appropriated as asked for.

MAY 5, FIRST GENERAL MEETING.

The association met in the Tulane Theatre, at 11 A.M., and was called to order by the president, DR. FRANK BILLINGS of Chicago.

Addresses of welcome were delivered by Hon. Paul Capdevielle, Mayor of New Orleans; Hon. Leon Jastremski of Baton Rouge, representing the Governor; and Henry P. Dart of the New Orleans Bar.

The responses to these addresses of welcome were delivered by DR. J. A. WITHERSPOON of Nashville, First Vice-President of the association.

PRESIDENT BILLINGS then delivered his annual address. He selected for his subject

MEDICAL EDUCATION IN THE UNITED STATES.¹

SECOND GENERAL MEETING.

DR. A. F. JONAS of Omaha, Neb., delivered the Oration on

SURGERY.²

HOUSE OF DELEGATES. — MAY 6.

DR. ARTHUR D. BEVAN, Illinois, presented the

REPORT OF THE COMMITTEE ON EDUCATION.

Among other things, the committee stated that the first step in advancing medical education should be the adoption of an educational requirement of membership, namely, the fixing of a minimum requirement, both as to preliminary education and as to medical education. This, in the opinion of the committee, should be:

(1) As a preliminary requirement, a high school education, sufficient to enable the student to pass the examinations for entrance to standard universities.

(2) A four-year medical course of at least seven months in each year. This requirement should become effective within five years, and apply to graduates of 1908 and after that date, sufficient notice

¹ See JOURNAL, May 7, p. 487.

² See JOURNAL, May 7, p. 493.

being thus given to all medical schools of the country, to enable them to change their curricula to meet these requirements.

The committee further suggested that it be the duty of the Committee on Education to secure (1) the adoption of the educational requirements determined upon by the American Medical Association, by each state medical society, and assist the state medical societies in securing the adoption of these educational requirements by each county medical society. (2) To see to it that all medical schools are thoroughly informed of the educational requirements of the American Medical Association, and to urge upon such schools as do not demand such requirements the necessity of doing so. (3) To inform themselves as to the requirements and character of work done by each medical school. (4) To inform themselves as to the laws governing the practice of medicine in each state, and as to the manner in which these laws are being enforced. (5) To inform the state examining boards and licensing bodies of the educational requirements of the American Medical Association, and urge those whose requirements are below those of the American Medical Association to adopt the higher requirements. (6) To inform themselves upon all matters pertaining to medical education. (7) To carry out the instructions of the House of Delegates in matters of medical education. (8) To make a full report on their work to the House of Delegates at each annual meeting.

This report was referred to the Business Committee. This committee recommended the adoption of the report; that it be referred to the Board of Trustees with the endorsement of the House of Delegates. It was so referred.

The report of the Provisional Committee, on the establishment of a National Bureau of Medicines and Foods, was recommitted to the original committee for further consideration.

The Manila Medical Society was accorded representation on the same basis as a state or territorial society, provided that its organization be extended to include the Island of Luzon and such other portions of the Philippines as may organize local medical societies.

The Business Committee recommended the appointment of a committee of three from the House of Delegates to co-operate with other bodies, looking towards placing a suitable memorial in Washington, commemorating the scientific achievements of Major Walter Reed.

Several amendments to the Constitution and By-Laws which were offered last year were adopted.

Dr. W. H. WELCH, Baltimore, offered resolutions in which he pointed out the importance of the President of the United States appointing as a member of the Isthmian Canal Commission a medical man possessed of the qualifications for this work. He said the association was convinced that the mere employment of a sanitary expert by the commission would not be likely to secure the desired results. The resolutions were referred to the Business Committee, and subsequently adopted by the House of Delegates. The secretary was instructed to transmit a copy of the resolutions to the President of the United States.

Dr. W. H. SANDARS, Alabama, offered the fol-

lowing, which were referred to the Committee on Public Health:

Whereas, The protection of the people from disease is the greatest aim of all true physicians; therefore, be it

Resolved, by the American Medical Association:

(1) That to formulate a complete, coherent and constitutional public health system for this country be declared one of the most important achievements to which this body can devote itself.

(2) That immediate steps be taken to construct such a system, and to submit it for adoption by the people of the states and of the nation.

The Committee on National Legislation in its report dealt with the Antivivisection Bill. The report was referred to the Business Committee, was reported back to the House of Delegates, with the recommendation that it be adopted. It was adopted.

Dr. H. N. MOYER, Illinois, offered the following resolution on behalf of the Business Committee:

Resolved, That the American Medical Association approve the action of its committee in defeating the Antivivisection Bill, recently pending before Congress, and that Congress be strongly urged to give no further consideration to legislation of that character in the future. [Unanimously adopted.]

Dr. J. N. MACCORMACK, Kentucky, presented his report as chairman of the Committee on Organization. At the conclusion of the report the representatives of forty-four states and territories made brief but very optimistic reports of the admirable work that was being done in organizing the profession throughout the country.

The Board of Trustees appropriated \$500 to defray the necessary expenses of the Committee on Organization.

HOUSE OF DELEGATES. — MAY 7.

The Board of Trustees appropriated \$500 for the scientific exhibit.

The Business Committee had considered carefully the report of the Committee on Prophylaxis of Venereal Diseases and the proposal to hold a congress during the Louisiana Purchase Exposition, and reported favorably upon the report of that committee, and on motion the report was adopted by the House of Delegates.

The Board of Trustees appropriated \$500 for the use of the Committee on Scientific Research.

The Board further reported that Dr. J. N. MacCormack of Kentucky had been continued as organizer of the association for the next twelve months on terms satisfactory to himself and the Board of Trustees.

In regard to the Rush Monument, the Board granted an allowance of \$500 to be used in defraying the expenses of unveiling.

Dr. E. ELIOT HARRIS, New York, presented the report of the enlarged committee on the revised Code of Ethics.

This enlarged committee consisted of the Special Committee and of one delegate from each state. The committee unanimously adopted the report entitled

THE PRINCIPLES OF MEDICAL ETHICS OF THE AMERICAN MEDICAL ASSOCIATION,

and recommended the same to the House of Delegates for adoption. The report of the committee was reached unanimously, without dissension or distrust on the part of its members, each aiming to formulate a result based on principle alone, and without regard to any past or present disagreements or misunderstandings whatsoever.

The report of the Committee on Code was unanimously adopted amid loud and prolonged applause.

The Committee on Transportation recommended that the next place of meeting be Atlantic City, N. J., and on motion this recommendation was concurred in by the House of Delegates.

DR. EDWIN WALKER, Indiana, President of the Mississippi Valley Medical Association, said that at the last meeting of this Association a resolution was unanimously passed declaring that it was desirable that it should become a distinct branch of the American Medical Association. He asked, therefore, that the matter be referred to the Committee on Organization.

DR. MACCORMACK, Kentucky, moved that the matter be referred to the Committee on Organization, and that authority be given the committee to consider the question of the division of this country into branch associations, in accordance with the plan laid down in the By-Laws, and that the committee be instructed to report on such a plan at the next annual meeting of the association. [Carried.]

MAY 6. — THIRD GENERAL MEETING.

DR. J. M. ANDERS, Philadelphia, delivered the

ORATION ON "MEDICINE."³

After its delivery DR. W. L. RODMAN, Philadelphia, spoke on the life work of the late Dr. Hunter McGuire of Richmond, Va., whose portrait had been presented to the association.

The following officers were elected for the ensuing year: *President*, DR. JOHN H. MUSSER, Philadelphia; *First Vice-President*, DR. G. C. SAVAGE, Nashville, Tenn.; *Second Vice-President*, DR. ISADORE DYER, New Orleans, La.; *Third Vice-President*, DR. C. LESTER HALL, Kansas City, Mo.; *Fourth Vice-President*, DR. GEO. F. JENKINS, Keokuk, Iowa; *Treasurer*, DR. HENRY P. NEWMAN, Chicago, Ill.; *Secretary*, DR. GEORGE H. SIMMONS, Chicago, Ill.

Trustees.—DR. WILLIAM H. WELCH, Baltimore, Md.; DR. MILES F. PORTER, Fort Wayne, Ind.; DR. M. L. HARRIS, Chicago, Ill.

Judicial Council.—DR. F. H. WIGGIN, New York City, N. Y.; DR. G. B. GILLESPIE, Tennessee; DR. D. C. PEYTON, Indiana.

Oration on Surgery.—DR. WILLIAM J. MAYO, Rochester, Minn.

Oration on Medicine.—DR. GEORGE DOCK, Ann Arbor, Mich.

Oration on State Medicine.—DR. H. M. BIGGS, New York City, N. Y.

Recent Literature.

DUDLEY, A.M., M.D., Professor of Gynecology, Northwestern University Medical School, Gynecologist to St. Luke's and Wesley Hospitals, Chicago, and WILLIAM HEALY, A.B., M.D., Instructor in Gynecology, Northwestern University Medical School. Chicago: The Year Book Publishers. 1903.

As stated in the introduction this small book of 242 pages is a careful *résumé* of the best practical literature of gynecology for year ending Feb. 1, 1903.

According to the publishers, the "Practical Medicine Series of Year Books" is published primarily for the general practitioner. This volume on gynecology should prove of value not only to the general practitioner but also to the specialist in diseases of women.

Coming from the author of one of the best recent textbooks on the subject, it is, as would be expected, abreast with the times. The typography is good and the illustrations are well executed. The book is to be strongly recommended to those who are interested in recent progress in this branch of medicine.

Obstinate Hiccough. By L. F. B. KNUTHSEN, M.D. 8vo. pp. x, 169. London: J. and A. Churchill. 1902.

The writer reports a case of obstinate hiccough under his own observation, in which the patient hiccoughed, as estimated, about half a million times. He then rehearses, in considerable detail, over a hundred and fifty cases laboriously collected from various sources, without any attempt to digest them or to make a critical study of the disorder. The case might have been condensed into such form as to be a suitable communication for a medical journal, but the necessity of a large volume on the subject is not apparent.

A Manual of Surgery. For Students and Practitioners. By WILLIAM ROSE, M.B., B.S. (Lond.), F.R.C.S., Professor of Clinical Surgery in King's College, London, and Senior Surgeon to King's College Hospital, etc., and ALBERT CARLESS, M.S. (Lond.), F.R.C.S., Surgeon to King's College Hospital, and Teacher of Operative Surgery in King's College, London, Examiner in Surgery to Glasgow University, etc. Fifth edition. New York: William Wood & Company. 1902.

This is the fifth edition of this work, and it is in England accepted as the best textbook of surgery. We have kept it some time on our desk as a reference book, and have found it to be of real value. In it the practitioner may find the essential points in diagnosis and treatment of practically all surgical lesions. The illustrations are not up to our American standard. In fact, they are poor. There are only a few of them that are original, and they do not compare with the best American textbooks of surgery. The text, however, is, as a rule, excellent. The etiology, pathology, symptoms, prognosis and treatment of injuries and diseases are thoroughly clear and practical. A judicious use of fine print has served two purposes: first, to place subjects of minor importance by themselves in fine print, and, second, to enable the authors to add a great deal of supplementary information. The book is one that we can heartily commend, as it is a safe guide to surgery.

The Practical Medicine Series of Year Books. Volume IV. Gynecology. Edited by EMILIUS C.

THE BOSTON

Medical and Surgical Journal

THURSDAY, MAY 21, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (INCORPORATED),
283 WASHINGTON STREET, BOSTON, MASS.

THE SIXTH CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

LACK of space in our last issue did not permit allusion to a number of matters of general interest at the Washington Congress held last week, to which we now desire to call attention. The weather during the three days' session was all that could be desired; the meetings were, in general, well attended, and many of the papers presented brought out vigorous discussion.

A communication which had been looked forward to with very particular interest was the final announcement by Dr. W. T. Councilman of the present state of the question relative to the etiology of smallpox, being the results of the work recently done at the Harvard Medical School by Drs. Councilman, Magrath, Brinckerhoff, Tyzzer and Thompson. The papers relating to smallpox were read before the Association of Pathologists and Bacteriologists in a room wholly inadequate to the demands made upon it. When the final paper on the subject by Dr. Councilman was announced, a large number of persons from other sections of the congress were obliged to stand in the small space available, and many of these left the room during the lantern demonstration, on account of the excessive heat. In spite of these drawbacks, the demonstration was enthusiastically received. Essentially the same points were emphasized in the life cycle of the organism as already described in these columns in our issue of April 30. The gap between the extra-nuclear and intra-nuclear forms was frankly admitted, but the belief definitely expressed that the organism described and pictured in many of its phases was the etiological factor of importance in the production of smallpox.

The discussion which followed this paper was most unfortunately cut short by the lateness of the

hour and the discomfort of the room; many left before it had begun, and only four men finally spoke out of many who presumably might have added something of commendation or criticism. Dr. Welch's remarks were naturally listened to with great attention, so firmly fixed has he become as an arbiter in matters relating to medical science. There could be no mistaking his statement that he fully accepted Dr. Councilman's results, and was willing to recognize the organism described by him as the cause of smallpox. He admitted, as Dr. Councilman had done, that there were gaps in our knowledge still to be filled before the complete life cycle of the organism could be established, but that the evidence remaining was so conclusive that no reasonable doubt could be entertained that the causative agent of the disease had been found.

Dr. James Ewing of Cornell University Medical School took a somewhat different point of view, and was inclined to lay stress upon the gaps in our knowledge, which, he maintained, must be satisfactorily filled before he could admit the proved relationship of the organism to the disease. He had been working on the subject for two years, had studied various cell-inclusions described by Dr. Councilman, and had finally concluded that they could not be regarded as standing in causal relation to the disease. He expressed himself as almost, though not quite, convinced that he was in the wrong by the work which had been presented, but still maintained that the intra-nuclear structures described as phases of a living organism might be otherwise interpreted. The arguments he used were reinforced by references to previous work, both of his own and of other men, and certainly gave the impression of soundness. These remarks of Dr. Ewing's, recognizing, as they did, the very high degree of suggestiveness of Dr. Councilman's work, still left a doubt as to its final complete conclusiveness, an attitude which should be welcomed as most conducive to a vigorous prosecution of the study, which all admit is necessary.

Heat and time and three hours' attention to abstruse topics closed the discussion after Dr. Ewing had spoken. However valueless informal remarks may at times be, it is certainly a matter of regret that this most important subject should not have been more thoroughly discussed at the public meeting. A fair statement of the present situation seems to be that there is a high degree of probability that the organism causing smallpox has been found; that further work is necessary before this probability can become an absolute certainty; that the work of Dr. Councilman and his associates has added materially to our knowledge of the protozoa as pathogenic organisms; and that we may look

forward with confidence to the early completed solution of the etiology of smallpox.

At the meeting of the Association of American Physicians, alcohol came in for its share of discussion, with the usual result that opinions remained divided, and probably more divided than at the beginning. There was agreement that alcohol predisposes to infection, but beyond this nothing definite was reached regarding its therapeutic value. This perennial controversy will no doubt go on for many years to come, but it is well to have the air cleared from time to time by vigorous expressions of opinion on the two sides. Dr. Theobald Smith made a significant addition to our knowledge of tuberculosis in man and animals by his paper on "Studies in Mammalian Tuberculosis." The discussion widely heralded by the daily papers on the subject of the Lorenz method of treatment for dislocation of the hip was treated judiciously by the orthopedic section, and was, on the whole, favorable to the method.

The general meetings of the Congress on pancreatic and biliary disease, combining as they did both medical and surgical interests, were well attended. Many excellent papers were read, several by foreigners of wide experience. Taken all in all, the social and scientific sides of the occasion were happily balanced.

THE SURGERY OF GALLSTONES.

It was not amiss that the surgery of the biliary passages received so prominent a place at the recent Congress of American Physicians and Surgeons at Washington. No surgical procedure has, in this community at least, been so gratifying as that of the removal of offending gallstones. So much had already been said and done that the propriety of early operations in the treatment of gallstones seemed as well-established a principle as the early treatment of appendicitis. Indeed, we had supposed that in offending gallstones, as in offending appendices, the question was not *whether* but *when* to remove them.

The accumulated experience of the surgeons at the Washington meeting was enormous. Kehr, with eight hundred cases of gallstone operations; Mayo, with five hundred and forty-seven, and others with hundreds, presented a basis for deductions the soundness of which it would be perhaps useless to question. It was the common experience, already expressed by English and American surgeons, that the fatalities in the surgery of the biliary passages are almost invariably owing to delay; that through delay not only do local changes take place, which make surgery un-

usually hazardous, but constitutional changes also, which make the prognosis still more unfavorable; that fatalities, therefore, are almost invariably caused by deep, difficult and bloody dissections, made imperative by acute emergencies, or by gradually increasing disabilities.

We are especially gratified by the reviving interest in this most attractive field of surgery, for we have long been convinced of the serious possibilities of gallstone disease; and, except for palliation, of the futility of medical measures. What was said with reference to early operations has been said in these columns time and again. Indeed, some of us have felt that the pleas for early operation in gallstones, like those for early operation in appendicitis, had become, by frequent repetition, somewhat tiresome.

We have long been convinced of the wisdom of the rule that offending gallstones should be removed at the earliest practicable moment, lest graver complications should demand graver measures; that gallstones should be sought when they are easily accessible in patients whose strength and condition insure immediate success, rather than when gallstones are with difficulty accessible in patients whose waning powers and unfavorable condition render recovery the exception. Such a rule—with certain exceptions, the necessity for which all will admit—we are glad to say has now met with general approval.

That gallstones may become latent, or spontaneously escape, we must allow; but the latent stone may become again active, and the undrained gall bladder, spontaneously evacuated, may become the nidus of other stones.

The hope of latency affords justification for medical treatment when local or constitutional evidence forbids operation. Less can, however, be said in favor of medicinal treatment to promote spontaneous evacuation when general conditions contraindicate surgical measures; for nothing can be more hazardous than the escape by natural means of a large stone, and nothing more unlikely than the effectual and total delivery of many smaller ones. Moreover, in the majority of cases stones vary extremely in size and number. The discovery of a hundred in the stools does not prove that many hundreds do not remain, or that a single large one may not, by retention and impaction, do more harm than many small ones.

Questions of recurrence of gallstones in the gall bladder or in the liver; of disabilities from adhesions; of local and general biliary infections; of pressure ulcerations of the impacted ducts, followed by strictures after freeing them; of the relations of gallstones to pancreatic disease; of appro-

prate surgical treatment and of prognosis, — all of these interesting questions are suggested in connection with the surgery of gallstones. Their solution will depend chiefly upon evidence found not only in operations upon the biliary passages themselves, but upon information gained in the course of other abdominal explorations. The general experience and the prevailing opinions expressed in Washington indicate in no uncertain fashion the brilliant possibilities of this interesting field of surgery.

OPPORTUNITIES FOR WORK IN PSYCHIATRY.

In the general reorganization which has recently taken place on the medical side of the New York State hospitals for the insane, it is well again to call attention to the fact that certain very desirable positions are open for young men who desire either a permanent or a temporary training in psychiatry and allied branches. The position which is available in a large number of these institutions bears the title of "clinical assistant." It requires no civil service examination, and leads at the end of a year to the possibility of more advanced positions to which salaries are attached. Applicants for these positions need not be citizens of New York State, nor, in fact, of this country; nor does a man in any way bind himself to continuance in the service, although naturally such a decision on his part, should he prove competent, is eminently desirable in the further development of psychiatry. In offering these positions it is the intention of those in authority to make them desirable for young medical men, who should be able thereby to increase their professional experience very widely.

It must always be remembered that large institutions of whatsoever character, wherein are housed a great number of individuals, must offer experience, not only in one particular disease or particular variety of diseases, but in everything to which flesh is heir. It is not for a moment to be supposed that a man entering for a year or more one of these institutions could fail to broaden his general medical knowledge on many other subjects than those immediately relating to psychiatry. Physical diagnosis, chemistry, pathological anatomy, research in various fields, as well as morbid psychology, would certainly be offered him in generous amount. It is rather remarkable that when such opportunities as these are offered, few suitable men are to be found to take them. The instinct of doing what others have done, rather than branching out in relatively new lines, is strong in the young medical man. He should, however, not fail to recognize the positive advantage to himself of one or more years spent in this sort of work.

The director of the Pathological Institute of the State of New York is desirous of obtaining such clinical assistants, for whom promotion, in the event of competency, is practically assured. The study of psychiatry has had many and peculiar difficulties to face, but we have no doubt that the time is not far distant when young men will enter this field with the same enthusiasm with which they now turn to surgical or other less difficult branches of medicine. We beg leave, therefore, to call the attention of men about to graduate from medical schools to these positions which are now open, and which offer a somewhat unique opportunity for research and general medical cultivation.

MASSAGE OF THE HEART AS A MEANS OF RESUSCITATION.

At a meeting of the Medical Association of the Greater City of New York held May 11, a paper of remarkable interest by Drs. Robert Coleman Kemp and A. W. Gardner, on "Experimental Researches on Resuscitation after Death from Chloroform," was read by Dr. Kemp. The experiments were made upon dogs, and for the first time manometric and kymographic tracings were presented in massage of the heart. At the same time, what is claimed as the first practical method for performing cardiac massage was described in the paper. This method is as follows: The animal is placed in the Nélaton (inverted) position, which throws the heart forward against the chest, and somewhat upward. An incision is made over, or slightly below, the apex. If necessary to secure more space, a small piece of the fifth and sixth ribs may be resected. The index and middle fingers are passed over the margin of the heart and behind it, near the apex, and pressure is made on the heart against the chest. Or, the opening being enlarged, the fingers may be placed behind, and the thumb between the apex and chest-wall, when the heart is rapidly squeezed between them. It was found that a rapid intermittent (double action) pressure resuscitated more cases, and, in effect, imitated the diastole of the pulse, as is shown in the tracings. A rapid single action pressure was not as successful. This method, the authors believe, is the most rational and by far the safest that has as yet been devised. An important part of the procedure is the maintenance of artificial respiration, and this was accomplished by means of the Kemp-Gardner modified intubation tube and a new pump devised for the authors by Mr. Hoyt, of the physiological laboratory of the College of Physicians and Surgeons. Prolonged infusion of hot normal saline solution was also employed. Resuscitation was accomplished in eleven out of

twenty-three animals, after absolute cessation of heart-action to sight, touch and compression, and this after the heart had remained in this condition for variable periods (3 to 16 minutes). The dogs lived from two to twenty-four hours, and in most of them the body functions returned to normal, and the animals became active and hard to control. The conviction was expressed that with a more perfect technique there was no reason whatever why death should occur at all.

Dr. Kemp also reported the first employment in this country of cardiac massage in a human subject. The case, however, was not one of chloroform syncope, and was unsuccessful. It was in every respect a most unfavorable one, as the patient was pyemic and, in addition, weakened by several previous operations. At the time the fatal collapse occurred Dr. Kemp had just done a simple operation not lasting over five minutes, for the opening of a large accumulation of pus in the left side of the abdomen, and nitrous oxide gas was the anesthetic employed. In conclusion, it was stated by the authors that they believed the procedure of massage of the heart to be both sound therapeutics and perfectly justifiable in all cases of death from chloroform or any other anesthetic, as well as from drowning and allied conditions, when all other means of resuscitation have failed.

MEDICAL NOTES.

THE WEATHER IN CHICAGO.—According to the *Bulletin* of the Chicago Health Department the mean March temperature was six degrees higher than the average of the previous thirty-one years, and that of April was one degree higher than the average, but the range in both months was excessive,—the lowest in March being thirteen degrees and the highest seventy-four degrees, with a difference of thirty-two degrees in twelve hours on the 18th. The maximum in April was seventy-eight degrees, the minimum twenty-eight degrees, with a sudden fall of fifty degrees in twenty-four hours on the 2d and 3d of the month. There were but twelve clear days in March and only ten in April, and while in both months the precipitation was more than the normal, it was so unevenly distributed that there has been no air-washing rainfall since April 11. The atmosphere is laden with "aerial sewage"; street sprinkling is inadequate, and the raw northerly and northwesterly winds that have prevailed for six weeks or more have continued if not aggravated the preventable respiratory diseases that have been endemic since the first of the year.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, May 20, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 31, scarlatina 31, typhoid fever 16, measles 42, smallpox 0.

BOSTON MORTALITY STATISTICS.—The number of deaths reported to the Board of Health for the week ending May 16 was 229 as against 204 the corresponding week last year, showing an increase of 25 deaths, and making the death rate for the week 20.37. The number of cases and deaths from infectious diseases was as follows: Diphtheria, 38 cases, 6 deaths; scarlatina, 45 cases, 1 death; typhoid fever, 18 cases, 1 death; measles, 53 cases, no deaths; tuberculosis, 24 cases, 26 deaths; smallpox, no cases, no deaths. The deaths from pneumonia were 39, whooping cough 2, heart disease 26, bronchitis 5, and marasmus 3. There were 7 deaths from violent causes. The number of children who died under one year was 49, under five years 63, persons over sixty years 47, deaths in public institutions 79.

A CENTENARIAN.—Thomas Grimes of South Boston, reputed to be one hundred and one years old, died May 16. He claimed to remember the Battle of Waterloo and Napoleon's exile to St. Helena, with many other historical events of ancient date.

CAMPAIGN AGAINST MOSQUITOS IN BROOKLINE.—The Brookline Board of Health has begun the work of exterminating mosquitos in that township. This work has met with gratifying success during the preceding two summers, and a systematic attempt will this year be made to treat catch basins and stagnant pools with crude oil. The appropriation for this work is estimated at about \$1,000. This attempt against the mosquito should certainly meet with every encouragement from municipal authorities, since there is no reasonable doubt that a very decided, if not complete, amelioration of the conditions might be attained with a relatively small outlay.

MEETING OF ASSOCIATION OF MILITARY SURGEONS.—The twelfth annual meeting of the Association of Military Surgeons of the United States began its sessions May 19, in Boston. Opening exercises were held in Faneuil Hall, presided over by Dr. Myles Standish, and addresses were made by Governor Bates, Dr. George E. Francis and others. Gen. Robert A. Blood of Boston delivered the annual address. The literary sessions were held at the Boston Medical Library, and a reception was

tendered the visiting physicians and invited guests Tuesday evening at the Cadet Armory. The committee on the Enno Sander prize medal announced that Major Frederick Smith of the Royal Army Medical Corps, Lancastershire, England, had received the first prize, and that Dr. William E. Rucker of the U. S. Marine Hospital Service had been awarded the second prize. Dr. Rucker was present and read his essay, which was well received. The general discussions of the meeting were of more than usual interest.

NEW YORK.

ADMINISTRATION OF DRUGS TO HORSES.—Although the administration of drugs to horses for the purpose of increasing their speed in races was officially prohibited some time ago, the practice appears to some extent, at least, to be still resorted to surreptitiously, and a flagrant instance of it, in which the perpetrator of the abuse quite overreached himself, has just been brought to light at the Morris Park race course, in the Bronx. A horse which, curiously enough, was named “Dr. Riddle,” was noticed to be acting in a very peculiar manner before the race for which he was entered, and although he started, the jockey riding him at once found it impossible for him to go on. Two hours later the animal died, and on the report of the veterinary sent to examine him, the license of the trainer who was responsible for his condition was promptly suspended, pending action by the stewards of the Jockey Club, and the case was reported to the Society for the Prevention of Cruelty to Animals.

NOTES FROM THE PHILIPPINES.

SANITARY DISTRICTS.—The commissioner of health, Major Carter, has lately divided the archipelago into seven sanitary districts, over each of which an American medical inspector has been placed. These districts are large, and include a number of provinces, or islands, each. The medical inspectors are directed to make full reports covering local sanitary conditions, both for the routine use of the board of health and also in relation to the combating of epidemics. All insular officials have been directed to show these inspectors every courtesy, and render them all possible assistance. The subjects to which special attention is to be paid, in addition to the general sanitary conditions, are the diseases common in each locality, the local death-rate and the chief causes contributing thereto. The history of the late cholera epidemic is to be studied, the customs and habits of the natives in relation to health, the diseases of cattle and live stock. Much attention will also be given to per-

fecting the organization of boards of health for the provinces and municipalities, and the instruction of their officials in the proper performance of their duties. The work to be done is of the utmost importance to the future efficiency of the health department for the islands. Heretofore the sanitary organization has been so loose in the provinces as not to permit of the best results, and the health officers in Manila found it difficult to direct sanitary work through the islands.

A CASE OF CONSPICUOUS GALLANTRY.—Conspicuous gallantry in action was lately displayed by Private Otto Herter, Hospital Corps, United States Army, in a fight between entrenched ladrones and a number of native scouts near Manila, in which there were over sixty killed on both sides. The strong entrenchments of the ladrones were charged by the scouts, and a desperate hand-to-hand combat took place with the well-armed ladrones. As it was impossible to succor the wounded during the *mêlée*, Private Herter seized a carbine from a scout and took a hand in the fight. His officers report that his shooting was remarkable, they personally seeing him kill six ladrones before a Remington bullet smashed his right humerus, when he drew his revolver with his left hand and continued in the action. After the fight he directed the treatment of the wounded, and then walked six miles to the nearest hospital for his own treatment. His arm was so badly injured that high amputation will be necessary. He has been recommended for a medal of honor, by his commanding officers, for his gallantry.

Miscellany.

METEOROLOGICAL RECORD.

For the week ending May 9, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

| Weymouth . . . | 11,344 | 4 | 0 | 25.00 | — | 25.00 | — | — | |
| Southbridge . . . | 11,268 | 5 | 1 | 20.00 | — | — | — | — | |
| Watertown . . . | 11,077 | 5 | 1 | — | — | — | — | — | |
| Plymouth . . . | 10,730 | 1 | — | — | — | — | — | — | |

Deaths reported, 3,593; under five years of age, 963; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 845, acute lung diseases 691, consumption 425, scarlet fever 60, whooping cough 49, cerebrospinal meningitis 10, smallpox 11, erysipelas 4, measles 52, typhoid fever 51, puerperal fever 15, diarrheal diseases 75, diphtheria and croup 84.

From whooping cough, New York 8, Chicago 8, Philadelphia 12, Baltimore 12, Pittsburg 8, Providence 2, Boston 5, and Springfield, Northampton, Marlborough, Westfield and Framingham 1 each. From erysipelas, Chicago 2, Philadelphia 1, Worcester 1. From smallpox, Chicago 4, Philadelphia 2, Pittsburg 4, Lawrence 1.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending April 25 the death-rate was 17.4. Deaths reported, 5,051; acute diseases of the respiratory organs (London) 280, whooping cough 124, diphtheria 66, scarlet fever 55, measles 168, smallpox 17.

The death-rate ranged from 4.9 in Kings-Norton to 30.7 in Middlesbrough; London 16.8, West Ham 15.0, Brighton 20.8, Portsmouth 13.4, Southampton 11.8, Plymouth 20.9, Bristol 13.8, Birmingham 19.4, Leicester 12.3, Nottingham 20.3, Bolton 22.0, Manchester 25.2, Salford 25.3, Bradford 15.5, Leeds 16.1, Hull 15.0, Newcastle-on-Tyne 18.1, Cardiff 12.1, Rhondda 19.2, Liverpool 21.2, Wigan 16.8, Croydon 14.4.

CHANGES IN THE MEDICAL CORPS OF THE NAVY
FOR THE WEEK ENDING MAY 16, 1903.

R. K. SMITH, passed assistant surgeon. Resignation accepted, to take effect May 19, 1903.

J. R. DYKES, U. S. N., acting assistant surgeon. Appointed assistant surgeon, April 18, 1903.

RECENT DEATHS.

RUFUS OSGOOD MASON, M.D., of New York, died suddenly on May 11, in his seventy-third year. He was born in Sullivan, N. H., and was graduated from Dartmouth College in 1854, and from the College of Physicians and Surgeons, New York, in 1859. During the Civil War he was an acting assistant surgeon. On hypnotism and subliminal consciousness, so-called, Dr. Mason was an authority, and some of his earlier experiments with hypnotism antedated those of Charcot. Although a busy general practitioner to the day of his death, he was much interested in literature and music, and was himself the author of several books. Among them were "Telepathy and the Subliminal Self," 1897, and "Hypnotism and Suggestion in Therapeutics," 1901. Quite recently there were published in the New York Times' Saturday Review of Books and Art two important articles by him on the late F. W. H. Myers' posthumous work, "Human Personality and Its Survival of Bodily Death."

DWIGHT S. CHAMBERLAIN, M.D., of Lyons, Wayne County, New York, died on May 11, aged sixty-five years, of typhoid pneumonia. During the Civil War he served as surgeon of the Ninth Heavy Artillery, and later was in charge of the Soldiers' Hospital at Syracuse, N. Y. At the time of his death he was president of the Lyons National Bank.

BOOKS AND PAMPHLETS RECEIVED.

How to Keep Well, an Explanation of Modern Methods of Preventing Disease. By Floyd M. Crandall, M.D. New York: Doubleday, Page & Co. 1903.

Transactions of the American Dermatological Association at its Twenty-sixth Annual Meeting, held in Boston, Mass., Sept. 18, 19 and 20, 1902.

Thirty-third Annual Report of the State Board of Health. 1902.

Transactions of the Twenty-fourth Annual Meeting of the American Laryngological Association, held at Boston, Mass., May 26, 27 and 28, 1902. New York: Rooney & Otten Printing Co. 1902.

The Duties of the Individual and the Government in the Combat of Tuberculosis. By S. A. Knopf, M.D., of New York. 1903.

Gonorrhea. By F. J. B. Cordeiro, A.B., M.D. 1903.

Quarantine Laws and Regulations of the United States. Revised edition. Washington, D. C.: Treasury Department. 1903.

Perineal Prostatectomy. A Special Method. By Parker Syme, M.D. New York. Reprint. 1902.

Albany Hospital. First Report of Pavilion F, Department for Mental Diseases, for the year ending Feb. 28, 1903. Reprint. 1903.

Operative Surgery. By Herbert William Allingham, F.R.C.S. Illustrated. New York: William Wood & Co. 1903.

Twenty-fifth Annual Report of the State Board of Health of the State of Connecticut, for the year 1902, with the Registration Report for 1901, relating to Births, Marriages, Deaths and Divorces. 1903.

Thirty-fourth Annual Report of the Secretary of State on the Registration of Births and Deaths, Marriages and Divorces in Michigan, for the year 1900.

The Practical Detail of Cataract Extraction. By H. Herbert, F.R.C.S. (Eng.). Major I. M. S. Illustrated. New York: William Wood & Co. 1903.

The Errors of Accommodation and Refraction of the Eye and their Treatment; a Handbook for Students. By Ernest Clarke, F.R.C.S. (Eng.), M.D., B.S. (Lond.). Illustrated. New York: William Wood & Co. 1903.

The Refraction of the Eye and the Anomalies of the Ocular Muscles. By Kenneth Campbell, M.B. (Edin.), F.R.C.S. (Eng.). Illustrated. New York: William Wood & Co. 1903.

Bacteria in Milk and its Products. Designed for the Use of Students in Dairying and for all Others Concerned in the Handling of Milk, Butter or Cheese. By H. W. Conn, Ph.D. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1903.

Mechanical Vibratory Stimulation, its Theory and Application in the Treatment of Disease. By Maurice F. Pilgrim, M.D. Illustrated. New York: The Lawrence Press. 1903.

Original Articles.

THE RELATION OF CHRONIC ENLARGEMENT OF THE SPLEEN TO ANEMIA IN INFANCY.*

BY JOHN LOVETT MORSE, A.M., M.D., BOSTON,

Instructor in Diseases of Children, Harvard Medical School; Assistant Visiting Physician at the City Hospital and at The Infants' Hospital, Boston.

The objects of this paper are to consider the relation of chronic enlargement of the spleen and anemia in infancy to each other, and whether or no there is any justification for the recognition of the special forms of anemia known as the "splenic anemia of infancy" and "anemia infantum pseudo-leukemika." Before taking up these subjects it may be well to consider briefly the peculiarities of the blood in infancy, both in health and disease, and the conditions under which chronic enlargement of the spleen occurs at this age.

The blood of infants under two years normally differs in certain of its characteristics from that of adults. The hemoglobin, although relatively high for a short time after birth, is, during the rest of childhood, relatively low. The number of red corpuscles is about the same or a little larger than in adults, averaging a little over five millions per cubic millimeter. During the first weeks of life there is more or less variation in the size and shape of the red cells, and nucleated forms are not very unusual. The number of white corpuscles per cubic millimeter is somewhat larger than in adults, averaging from ten thousand to fourteen thousand. The relative proportions of the various forms of leucocytes are also considerably different. The limits are roughly as follows: Small mononuclear, 50% to 70%; large mononuclear, 5% to 15%; polynuclear neutrophils, 30% to 40%; eosinophiles, 1% to 10%; that is, the proportion of mononuclear forms is about three times as great as in adult life, while that of the polynuclear neutrophils is only one half as large. The mononuclear cells, moreover, are not merely lymphocytes, but vary much, not only in the size of the cell as a whole, but also in the size of the nucleus and in the amount of protoplasm.

Blood changes develop more easily and more frequently as the result of various morbid conditions and diseases in infants than in adults. All the changes seen in the blood of adults as the results of disease are exaggerated in infancy. The tendency is always to revert to a younger or to the fetal type of blood. All forms of blood disease in infancy are apt to be associated with splenic enlargement. As the result of this tendency to exaggeration of changes and to reversion to a younger type of blood, the red corpuscles show much greater variety in size and shape and many more nucleated forms than under similar pathological conditions in the adult. Leucocytosis also develops more rapidly and to a greater degree. Its type, moreover, is not constant, as in adults, in whom the increase of white cells is largely in the polynuclear neutrophils. In infants the increase is sometimes in the lymphocytes, sometimes in the large mononuclear forms, sometimes in the polynuclear neutrophils, and sometimes, even, in the eosinophiles. Leucocytosis is more apt to occur in blood conditions associated with splenic enlargement than in

those without it. Myelocytes occur in less severe conditions and in greater numbers than in adults. An increase in the number of eosinophilic cells, even if considerable, seems to be of little significance. The percentage of hemoglobin is almost always relatively low.

Chronic splenic tumor is much more common in infancy than in later years, occurring not only under the same conditions as in adults, but in many others not associated in them with splenic enlargement. It is, as in adults, an almost constant accompaniment of leukemia, pseudo-leukemia, cirrhosis of the liver and malaria. These conditions, with the exception of malaria, are extremely rare in infancy. Malaria, however, is not at all uncommon. In it the splenic tumor develops early, attains considerable size and persists a long time. Enlargement of the spleen from amyloid change occurs in association with amyloid changes in other organs as in adults and from the same causes. Malignant disease of the spleen is almost unknown in infancy, but does occur. If so, it is usually congenital or secondary to malignant disease elsewhere. Primary endothelial hyperplasia of the spleen (Bovaird) has not yet been seen under two years.

In adults chronic diseases are not, as a rule, associated with enlargement of the spleen. Many of the chronic affections of infancy, however, especially those in which cachexia is marked, are accompanied by enlargement of the spleen. It is in this class that the enlargements of the spleen in syphilis and rachitis probably belong. It is almost invariably enlarged in the hereditary syphilis of infancy. This enlargement is usually due to an increase in the stroma and to thickening of the blood vessels, but may in rare instances be due to gummatous changes. Enlargement of the spleen occurs very commonly in rickets. Its direct dependence on the disease *per se* is, however, doubtful. In tuberculosis the enlargement, unless due to amyloid changes, is usually slight. It is especially common in conditions associated with anemia, all forms of which, whether primary or secondary, may be associated in infancy with enlargement of the spleen.

Before going further it may be well to attempt to define what is meant by the terms "splenic anemia of infancy" and "anemia infantum pseudo-leukemika." Certain authors, usually English, have apparently considered chronic enlargement of the spleen *per se* as sufficient to justify the use of the term "splenic anemia." Most of the others have, however, evidently used the term to describe the clinical complex more commonly known as "anemia infantum pseudo-leukemika." There can be but little doubt that the terms "splenic anemia of infants," "anemia splenica infantile," "anemia splenica infettiva dei bambini" and "anemia infantum pseudo-leukemika" have been applied to practically identical conditions and may be considered as synonymous. No two authors are agreed as to just what are the pathognomic symptoms, physical signs and blood condition of anemia infantum pseudo-leukemika. A combination of the descriptions of Von Jaksch, Luzet and Alt and Weiss describes it as well, perhaps, as anything. (Dr. A. H. Wentworth¹ has

+ = slight; ++ = moderate; +++ = marked.

recently reviewed the literature of this condition very thoroughly.)

It is a form of severe progressive anemia of infants whose symptoms and clinical course correspond to the picture of leukemia. There is marked enlargement of the spleen and more or less enlargement of the liver. The superficial lymph nodes are usually enlarged. The course is less rapid and the prognosis better than in leukemia. The blood condition is as follows: Constant diminution in the number of red corpuscles with a more or less marked diminution in the amount of hemoglobin; poikilocytosis; very many nucleated red cells, chiefly normoblasts, many of these of abnormal form and showing karyokinetic figures; more or less polychromatophilia of the nucleated red cells and many of the non-nucleated; pretty marked leucocytosis, always polymorphons.

Pathological examinations have been few in these cases, and, as a rule, very incomplete. The lesions which have been described in the spleen are almost entirely those of chronic hyperplasia, affecting various parts of the organ in different degrees in individual cases. The livers showed congestion and slight increase in the connective tissue. In some cases there was a slight infiltration of lymphoid cells and in others slight degenerative lesions.

I have notes, with complete examinations of the blood, on twenty-two cases of chronic enlargement of the spleen in infancy, as well as notes without examinations of the blood on a number of others. For lack of a better basis I have arranged them "primarily" according to the size of the spleen, and secondarily according to the size of the liver.

CASE I.—Joseph C., eleven months old, was admitted to the Infants' Hospital Jan. 3, 1901. He had had the breast alone for six months, after that a varied diet. He had always vomited a great deal. The history was otherwise imperfect.

He was well developed, fairly nourished and flabby. The skin was in good condition. There was marked pallor of the skin and mucous membranes. The fontanelle was level. There were two lower incisors. There was a moderate rosary. The cardiac impulse was in the fifth space $1\frac{1}{2}$ cm. outside the nipple line. The upper border of cardiac dullness was at the lower border of the second rib, the right border 3 cm. to the right of the median line, the left $7\frac{1}{2}$ cm. to the left of the median line. The first sound over the whole precordia was continued into a soft, blowing murmur. The second pulmonic sound was the louder. The lungs were negative. The spine showed a marked curve of weakness. The upper border of liver flatness was in the fifth space. The lower border was palpable 4 cm. below the costal border in the nipple line. The spleen was palpable 1 cm. below the costal border. There was a slight umbilical hernia. There was a slight enlargement of the epiphyses at the wrists. The extremities were otherwise normal except for slight edema of the feet and legs. There was no edema of the hands, but a little of the eyelids.

Urine: Pale, clear, acid, 1017, no albumin. Blood: extremely watery and streaky, coagulation very slow; hemoglobin, 15%; red corpuscles, 1,250,000; white corpuscles, 10,300; small mononuclear, 67%; large mononuclear, 2%; polynuclear neutrophiles, 29%; eosinophiles, 2%. There was marked variation in the size and shape of the red corpuscles. There was a tendency to small forms rather than to large. No nucleated forms were seen in two slides.

In spite of careful feeding, iron and arsenic, he failed steadily in weight, strength and color. The temperature was slightly elevated. There was almost no vomiting. The movements were clay-colored. The edema of the face increased.

He died Feb. 3, 1901.

CASE II.—William F., aged ten months, came to the Out-Patient Department of the Infants' Hospital May 17, 1898. There was no history of tuberculosis in the family or of exposure to it. He had nothing but breast milk, but was fed irregularly. A rough analysis of the breast milk showed a specific gravity of 1031 and 2.6% fat. The proteids must, therefore, have been about normal or a little low. He began to lose weight, strength and color at seven months, and had failed steadily since then. He had had no fever. The bowels moved once daily. He vomited a little almost every day.

He was poorly developed and nourished. Pallor was marked. The head was negative. There were two teeth. He held up his head, but was unable to sit alone. There was a moderate rosary. The heart and lungs were normal. By auscultatory percussion the stomach was distended. The liver was normal. The spleen was palpable 2 cm. below the costal border. The extremities were normal. There was a slight general enlargement of the lymph nodes.

Blood: Hemoglobin, 42%; red corpuscles, 3,288,000; white corpuscles, 4,800; small mononuclear, 49%; large mononuclear, 5%; polynuclear neutrophiles, 45%; eosinophiles, 1%. There was moderate variation in the size and shape of the red corpuscles. One macroblast and one normoblast were seen in counting 100 white cells.

When last seen, June 22, 1898, the symptoms had continued, and he had failed steadily in every way. He presumably died shortly after.

CASE III.—Joseph E., five months old, came to the Out-Patient Department of the Infant's Hospital May 9, 1898. He had never had any food but breast milk. He vomited after almost every nursing. The bowels were constipated. He had never gained.

He was small but not much emaciated. The pallor was marked. The head was negative. He was unable to hold it up. There was a marked rosary. The heart was normal except for a systolic murmur over the whole precordia. A few râles were heard here and there in both chests. The abdomen was lax. The liver was normal. The spleen was palpable about 2 cm. below the costal border. The epiphyses at the wrists were slightly enlarged. The extremities were otherwise normal. There was a slight general enlargement of the lymph nodes.

Blood: Hemoglobin, 57%; red corpuscles, 4,519,000; white corpuscles, 15,000; small mononuclear, 44%; large mononuclear, 3.5%; polynuclear neutrophiles, 47%; eosinophiles, 5.5%. There was but little variation in the size of the red corpuscles and very little in their shape. One normoblast was seen in counting 400 whites.

He died Nov. 25, 1896 "of the same trouble."

CASE IV.—Joseph M., was admitted to the Infants' Hospital in May, 1900, when sixteen months old. He had been fed on condensed milk and malted milk, and had never done well. He had always had vomiting and diarrhea off and on, and had never gained.

He was small, thin and markedly pale. The fontanelle was small and much sunken. There were eleven teeth. The costal cartilages were much depressed, making the front of the chest flat. There was a moderate rosary. The heart and lungs were normal. There was a loud systolic blow in the neck. The abdomen was lax. The liver was normal. The spleen was palpable about 2 cm. below the costal border over a distance of 5 cm. The edge was sharp and the notch distinctly felt. The extremities were normal. There was a moderate general enlargement of the lymph nodes, especially of those in the right side of the neck.

Blood: Hemoglobin, 25%; red corpuscles, 2,296,000; white corpuscles, 16,850; small mononuclear, 34.4%; large mononuclear, 19.6%; polynuclear neutrophiles, 44.4%; eosinophiles, 0.4%; myelocytes, 1.2%. The red corpuscles were somewhat irregular in size, shape and color, but poikilocytosis was not marked. In counting 250 white corpuscles, 6 normoblasts, 1 microblast and 1 normoblast were seen. After a few weeks of observation he was discharged to die.

He was seen Sept. 8, 1902, two and one half years later. He was then well and strong and of good color. The liver was normal. The spleen was not palpable.

CASE V.—Francis K., aged sixteen months, was admitted to the Infants' Hospital Jan. 12, 1901. He was well until

he was weaned at fourteen months and put on general diet. After that he was constipated, vomited occasionally and lost weight pretty steadily. When weaned he could stand and walk with the aid of a chair. At entrance he was unable to stand.

He was well developed and nourished, but slightly flabby and rather pale. The fontanelle was 3 cm. in diameter. The head was not otherwise abnormal. There were twelve teeth. The spine showed a slight curve of weakness. There was a slight rosary and slight flaring of the lower chest. The heart showed nothing abnormal excepting a faint systolic murmur in the pulmonic area. There was a venous hum in the neck. The lungs were normal. The upper border of the liver flatness was at the fifth rib. The lower border was palpable 3 cm. below the costal border. The spleen was palpable 2 cm. below the costal border and was 4 cm. in width. The abdomen was negative. There was slight enlargement of the epiphysis at the wrists.

Urine: Normal color, alkaline, no albumin. Blood: Hemoglobin, 65%; red corpuscles, 5,072,000; white corpuscles, 16,600; small mononuclear, 40%; large mononuclear, 18%; polynuclear neutrophiles, 41%; eosinophiles, 1%. There was moderate variation in the size of the red corpuscles, but little in their shape. No nucleated forms were seen. No abnormal forms of white cells were seen, but there was great variation in the size of the mononuclear cells, very few of them being small.

He was discharged Jan. 19, 1901, improving in every way. He did not vomit, his movements were normal, and he was gaining in weight. Nothing further is known as to the progress of the case.

CASE VI. Alice F., aged five months, came to the Out-Patient Department of the Infants' Hospital June 22, 1897. She had always been fed on sterilized milk or condensed milk. She had always vomited and had undigested movements. She had gained fairly steadily in weight.

She was fairly developed and nourished and very pale. The heart was normal except for a systolic murmur over the whole precordia. The lungs were normal. The liver was normal. The spleen was palpable 3 cm. below the costal border and was 4 cm. wide. There was a slight umbilical hernia. There was a general enlargement of the lymph nodes more marked in those of the groin.

Blood: Hemoglobin, 25%; red corpuscles, 1,736,000; white corpuscles, 4,200; small mononuclear, 69%; large mononuclear, 5%; polynuclear neutrophiles, 25%; eosinophiles, 1%. There was marked variation in the size and moderate variation in the shape of the red corpuscles. No nucleated forms were seen.

Nothing further is known as to the progress of the case, except that she died July 20, 1897.

CASE VII. Helen G., ten months old, came to the Out-Patient Department of the Infants' Hospital July 2, 1897. She was about a month premature. She was nursed for five months, and then given condensed milk with cereals. She had never been strong, and had always been constipated. She was brought because of fever, crying and sleeplessness for a month.

She was well developed and nourished, but of a very pale, lemon-yellow color. She had no teeth. There was a slight rosary. There was a slight systolic murmur over the whole precordia. The lungs were normal. The liver was not enlarged. The spleen was palpable 3 cm. below the costal border and was 6 cm. wide. There was a slight general enlargement of the lymph nodes.

Blood: Hemoglobin, 30%; red corpuscles, 3,708,000; white corpuscles, 18,520; small mononuclear, 31%; large mononuclear, 4%; polynuclear neutrophiles, 64%; eosinophiles, 1%. There was marked variation in the size and shape of the red corpuscles, many of them being very large. Five normoblasts were seen in counting 500 whites.

She was last seen July 29, 1897, and at that time was doing well in every way.

CASE VIII. Joseph D., aged twenty-one months, was admitted to the Infants' Hospital June 9, 1902. No history came with him.

He was well developed and nourished, but flabby. The anterior fontanelle was 2 cm. in diameter. The frontal and parietal eminences were somewhat enlarged. There were twelve teeth. There was a marked rosary and a slight

retraction of the ribs at the insertion of the diaphragm. The heart and lungs were normal. The level of the abdomen was much above that of the thorax. The liver was palpable 3 cm. below the costal border. The spleen was palpable 3 cm. below the costal border and was 4 cm. wide. The surface was smooth, the edge sharp, the notch palpable. The extremities were normal excepting for considerable enlargement of the epiphyses at the wrists. There was a slight general enlargement of the lymph nodes.

Blood: Hemoglobin, 65%; red corpuscles, 5,380,000; white corpuscles, 15,625; small mononuclear, 43%; large mononuclear, 2%; polynuclear neutrophiles, 54%; eosinophiles, 0.5%; myelocytes, 0.5%. There was slight variation in the size and shape of the red corpuscles. No nucleated forms were seen.

He was lost sight of, and nothing is known as to the further history.

CASE IX. Sylvia V., aged eleven and one-half months, entered the Infants' Hospital May 27, 1899. Nothing was known as to her history except that she had had whooping cough in February. There was not much cough at that time but the appetite was poor, she vomited occasionally and had a sore mouth.

She was markedly emaciated and very pale. There was a systolic murmur over the whole precordia. There was an occasional rale in both chests. The liver was normal. The spleen was palpable about 3½ cm. below the costal border. There was a slight general enlargement of the superficial lymph nodes. The body and extremities were covered with a fine purpuric eruption. The eyelids were puffy. There were a few hemorrhagic spots in the mouth. There was no edema of the extremities.

Blood: Markedly pale and yellow. Hemoglobin, 19%; red corpuscles, 950,000; white corpuscles, 27,000; small mononuclear, 52%; large mononuclear, 13%; polynuclear neutrophiles, 32%; eosinophiles, .5%; myelocytes, 2.5%. There was marked variation in the size and moderate variation in the shape of the red corpuscles. In counting 500 white cells, 22 megaloblasts, 8 microblasts, 24 normoblasts and 12 atypical nucleated red cells were seen.

She took but little food and vomited a great deal. The movements were fairly normal. The temperature rose steadily and she died June 1, 1899.

CASE X. Sadie C., aged twenty months, came to the Out-Patient Department of the Infants' Hospital, June 20, 1896. She was fed at first on the breast, but was soon given patent foods and then put on a general diet. She had always had more or less trouble with the digestion. She could sit and stand alone, but was unable to walk.

She was fairly developed and nourished, but flabby and pale. She had a large, square, flat head. The fontanelle was nearly closed. There were eleven teeth. There was a marked curve of weakness. There was a very marked rosary, pigeon breast and marked retraction of the ribs at the insertion of the diaphragm. The heart and lungs were normal. The liver was not enlarged. The spleen was palpable about 4 cm. below the costal border and was 8 cm. wide. The abdomen was large and soft. There was marked enlargement of the epiphyses at the wrists and moderate bow-legs. There was a slight general enlargement of the lymph nodes.

Blood: Hemoglobin, 68%; red corpuscles, 5,158,000; white corpuscles, 15,200; small mononuclear, 51%; large mononuclear, 5%; polynuclear neutrophiles, 40%; eosinophiles, 4%. There was considerable variation in the size and shape of the red corpuscles. Macrocytes were numerous. An occasional normoblast was seen.

She was seen Oct. 7, 1902, when a little more than seven years old. She was then perfectly well. The tip of the spleen was just palpable.

CASE XI. Minnie B., eighteen months old, was admitted to the Infants' Hospital Jan. 1, 1902. No history came with her.

She was fairly developed and nourished, but flabby and rather pale. The fontanelle was nearly closed. The parietal eminences were enlarged. There were twelve teeth. There was a slight rosary and flaring of the lower ribs. The heart and lungs were normal. The upper border of the liver flatness was at the fifth rib, the lower border was palpable 6 cm. below the costal border. The spleen was palpable 4 cm. below the costal border. The surface was

smooth, the consistency firm, the edge rounded and the notch distinct. The epiphyses at the wrists and ankles were enlarged and there was slight bow-legs. There was a slight general enlargement of the lymph nodes.

Urine: Normal, acid, 1012, no albumin. Blood: Hemoglobin, 75%; red corpuscles, 5,650,000; white corpuscles, 11,800; small mononuclear, 32%; large mononuclear, 8%; polynuclear neutrophils, 51%; eosinophiles, 9%. There was very slight variation in the size of the red corpuscles and none in their shape or staining reaction. No nucleated cells were seen.

She was seen Aug. 7, 1902. She was then perfectly well. The liver was palpable 4-1-2 cm. below the costal border in the nipple line. The spleen was not palpable.

CASE XII. Catherine A., twelve months old, was admitted to the Infants' Hospital April 23, 1902. She had been fed on patent foods after the first two months. Her appetite had been poor. She had always vomited and had had bad movements.

She was fairly developed and nourished, but pale. The frontal eminences were a good deal enlarged. The anterior fontanelle was 2 cm. in diameter and somewhat depressed. There was no craniotabes. There were two teeth. There was a purulent discharge from the left ear. There was a moderate rosary. The heart was normal. There was an occasional moist rale in both lungs. The level of the abdomen was above that of the thorax. The liver was palpable 2 cm. below the costal border. The spleen was palpable, running out from beneath the costal border just inside the left nipple line, downward to the level of the umbilicus and then backward into the flank. The surface was smooth and hard and the edge sharp. The notch was not made out. There was slight enlargement of the epiphyses at the wrists. There was a slight general enlargement of the lymph nodes.

Urine: pale, no albumin. Blood: hemoglobin, 60%; red corpuscles, 3,564,000; white corpuscles, 16,250; small mononuclear, 31%; large mononuclear, 8%; polynuclear neutrophils, 60%; eosinophiles, 1%. There was marked variation in the size, shape and staining reaction of the red corpuscles. One megaloblast was seen while counting 100 whites.

She remained in the hospital about two weeks. While there she had very little fever and the lungs cleared up. The movements became normal and vomiting ceased.

She was seen Dec. 19, 1902, eight months later. Her general condition was much improved. She was scarcely able to sit up alone. The liver was normal. The spleen was not palpable.

CASE XIII. Sam S., eight months old, was admitted to the Infants' Hospital, May 11, 1902. He had always been breast-fed, but for the last three months had had more or less vomiting and been constipated.

He was fairly developed and nourished. Pallor was moderate. The fontanelle was level and 2 cm. in diameter. There were no teeth. There was a marked rosary and slight flaring of the lower chest. The heart and lungs were normal. The upper border of liver flatness was in the sixth space. The lower border was palpable 3 cm. below the costal border in the nipple line. The spleen was palpable, running out from beneath the costal border in the anterior axillary line, downward to the level of the umbilicus and upward into the flank behind the posterior axillary line. The surface was smooth, the edge sharp, the notch palpable. The abdomen was much enlarged, but lax. There was marked enlargement of the epiphyses at the wrists. There was a slight general enlargement of the lymph nodes.

Urine: high, acid, trace of albumin. Sediment: many pus cells and rarely a hyalin and granular cast. Blood: hemoglobin, 00%; red corpuscles, 5,800,000; white corpuscles, 15,000; small mononuclear, 43%; large mononuclear, 2%; polynuclear neutrophils, 55%; eosinophiles, 0. Typical signs of meningitis developed a little later, and the child died after an illness of a few days.

CASE XIV. Helen P., seven months old, was admitted to the Infants' Hospital in January, 1902. Although she was breast-fed up to two weeks before entrance she had never done well after the first month. She had always vomited, had usually been constipated, but

sometimes had had diarrhea. For the last two weeks she had been fed on Eskay's food.

She was small and poorly nourished. The skin was desquamating. There was a marked yellowish pallor. The fontanelle was level. There was a venous hum in the neck. There was a very slight rosary. The heart area was normal. The first sound over the whole precordia was continued into a blowing murmur, loudest and longest at the pulmonic area. The lungs were normal. The upper border of liver flatness was at the fifth rib. The lower border was palpable 3 cm. below the costal border. The spleen was palpable, running out from behind the costal border about midway between the anterior axillary line and the nipple line, forward and downward to the level of the umbilicus in the nipple line, and backward into the flank. The surface was smooth and hard, the edge sharp, the notch palpable. The abdomen was negative. There was a considerable general enlargement of the lymph nodes. There were a few purpuric spots on the head, face and legs, and a fine purpuric rash on the arms.

Urine: straw colored, slightly acid, no albumin. Blood: hemoglobin, 55%; red corpuscles, 2,553,000; white corpuscles, 8,200; small mononuclear, 41%; large mononuclear, 4%; polynuclear neutrophils, 50%; eosinophiles, 1%; myelocytes, 1%. There was moderate variation in the size and shape of the red corpuscles with a tendency to large, but not to oval forms. There was moderate variation in the staining characteristics of the red corpuscles.

She remained in the hospital about two weeks. She took her food poorly and vomited a good deal. The movements, however, were fairly normal. She lost weight steadily. At the time of discharge the blood showed: Hemoglobin, 70%; red corpuscles, 3,260,000; white corpuscles, 13,125. She was heard from in August, 1902. She was then "perfectly well."

CASE XV. Alice C., ten months old, was brought to the Out-Patient Department of the Infants' Hospital July 14, 1897. She had always been fed on various "infant foods." She had never thrived, and had gained little or no weight. During the last few weeks she had lost both weight and strength. She had always vomited a good deal. She had had diarrhea for the first few months but since then had been constipated, the movements being normal in color. Bunches were noticed in the neck and groins at five months; they had not increased markedly since. Depressed fontanelle, dryness of the skin and nocturnal fever had been present for three months. A tumor was first noticed a week before she came to the hospital. It had increased somewhat in size during this time.

She was poorly developed and emaciated. The skin was dry and brownish. The frontal bones were considerably lower than the parietal. The fontanelle was depressed and small. The frontal eminences were large. There were no teeth. There was a slight rosary. The heart and lungs were normal. There was dullness under the upper part of the sternum, but none at the root of the lungs. The upper border of liver flatness was at the sixth rib. The lower border was palpable 5 cm. below the costal border. The edge of the liver was firm and sharp. The spleen was palpable, running out from under the ribs in the left nipple line downward to the umbilicus and then backward into the flank just above the anterior-superior spine. The surface was smooth, the consistency firm, the notch palpable. There was marked enlargement of all the superficial lymph nodes.

Blood: hemoglobin, 60%; red corpuscles, 4,340,000; white corpuscles, 31,500; small mononuclear, 29.5%; large mononuclear, 9.9%; polynuclear neutrophils, 56.5%; eosinophiles, 0.3%; myelocytes, 3.8%. There was very marked variation in the size and shape of the red corpuscles. Nucleated forms were very numerous. Of 100 nucleated cells 89 were macroblasts and 11 normoblasts. Six macroblasts showed nuclear figures. Many of the nucleated and some of the non-nucleated forms were polychromatophilic.

She was again seen Aug. 9. At that time the spleen had diminished considerably in size. She died Sept. 18. The mother wrote that she had had a hemorrhage from the bowels for two weeks before death, and that "the bunch in the side could not be felt."

CASE XVI. Charles G., ten months old, came to the Out-Patient Department of the Infants' Hospital July 11, 1898. He had been fed on the breast and condensed milk at home and had had cows' milk at a day nursery. He had always had more or less diarrhea and vomiting, varying in severity from time to time. At times he seemed sick, at others not. He was always backward, and his head perspired profusely at night. There had been a gradual increase in the size of the abdomen for two months.

He was fairly developed but poorly nourished. His color was fair, the skin dry. The anterior fontanelle was large. There was no craniotabes. There was a purulent discharge from the nose. He had two teeth. He could hold up his head, but was unable to sit alone. There was a marked rosary and flaring of the lower ribs. The heart and lungs were normal. The liver flatness began at the eighth rib in the scapular line; the lower border was palpable 5 cm. below the costal border. The spleen could be felt running out from under the ribs in the nipple line, directly downward to the level of the umbilicus, backward at a right angle into the flank and upward in the posterior axillary line. The edge was sharp and hard, the surface smooth. The abdomen was considerably enlarged and rather tense. The epiphyses at the wrists were considerably enlarged, but the extremities were otherwise normal. There was a slight general enlargement of the lymph nodes.

Blood: hemoglobin, 58%; red corpuscles, 4,408,000; white corpuscles, 47,220; small mononuclear, 36.5%; large mononuclear, 9.5%; polynuclear neutrophiles, 50.5%; eosinophiles, 1%; myelocytes, 2.5%. There was moderate variation in the size and staining qualities of the red corpuscles, but very little in their shape. In counting 500 white corpuscles, 12 normoblasts, 1 microblast and 18 macroblasts were seen.

He was soon lost sight of, and nothing is known as to the further history of the case.

CASE XVII. Maude M., eight months old, was admitted to the Infants' Hospital May 14, 1899. She undoubtedly had congenital syphilis. There was no further history.

She was small, pale and poorly nourished. The head was somewhat flattened, the frontal and parietal eminences enlarged. The anterior fontanelle was 3 cm. in diameter and bulging. The superficial veins of the scalp were considerably enlarged. The nares were occluded, and there was considerable purulent discharge. The mouth was open, and the mouth and throat dry. There were no teeth. She held her head up feebly, but could not sit alone. There was a very slight rosary. The heart and lungs were normal. The lower border of the liver was palpable 6 cm. below the costal border. The spleen could be felt coming out from behind the ribs in the anterior axillary line running downward to the level of the umbilicus and backward under the ribs at about the posterior axillary line. The surface was smooth, the edge sharp, the notch palpable. The abdomen was rather large. The extremities were normal except that the skin of the soles was dry and cracked. There was a general enlargement of the lymph nodes including the post-auricular and epitrochlear, to the size of beans.

Blood: hemoglobin, 65%; red corpuscles, 4,200,000; white corpuscles, 13,400; small mononuclear, 42%; large mononuclear, 11%; polynuclear neutrophiles, 45%; eosinophiles, 2%. There was moderate variation in the size of the red corpuscles, but little in their shape and staining reaction. No nucleated forms were seen.

She was discharged May 19, 1900. Nothing further is known as to the history of the case.

CASE XVIII. Minnie L., seventeen months old, was admitted to the Infants' Hospital Nov. 13, 1895. She had never been nursed, but had been fed on condensed milk. She did not vomit. The bowels moved once in three or four days. The movements were large, hard, whitish, foul and contained a little mucus. A hard lump had been noted in the abdomen for two months. It was as large when first discovered as at admission. She had been pale for a long time, and had lost flesh rapidly in the last three months. She was just beginning to sit up alone.

She was fairly developed and emaciated. There was

marked pallor with a yellowish tinge. The fontanelle was not closed. She had four teeth badly decayed. There was a moderate rosary. The heart and lungs were normal. The liver was normal. The spleen reached nearly to the median line, and extended to about 1 cm. above the anterior-superior spine. The abdomen was full and tense. There was an umbilical hernia. There were a few purpuric spots on the abdomen. The epiphyses at the wrists and ankles were enlarged.

Urine: normal. Blood: hemoglobin, 60%; red corpuscles, 3,556,000; white corpuscles, 12,400; small mononuclear, 28%; large mononuclear, 10%; polynuclear neutrophiles, 55%; eosinophiles, 7%. There was marked variation in the size and shape of the red corpuscles. Macrocytes were more numerous than microblasts. There was a moderate number of nucleated red corpuscles, macroblasts being the most numerous. There was an occasional free nucleus. There were no abnormal forms of white cells.

She was heard from July 29, 1902, when about eight years old. She was said to be perfectly well in every way.

CASE XIX. Jennie R., ten months old, was admitted to the Infants' Hospital June 1, 1901. She was breast-fed for five weeks, after that she was fed on a modified milk prepared at home. This mixture was a weak one and was not changed for seven months. During this time she had no gastro-enteric disturbances, but had gained weight very slowly. From this time until entrance, although still on a stronger modified milk, she had more or less disturbance of the bowels.

She was fairly developed and nourished. There was moderate pallor of the skin and mucous membranes. The anterior fontanelle was 3 cm. in diameter and level. The head was flattened on top and behind. There were two teeth. She sat alone, feebly. There was a moderate rosary. There was slight retraction of the chest at the insertion of the diaphragm. The heart and lungs were normal. The abdomen was distended. There was a slight umbilical hernia. The upper border of the liver flatness was at the upper border of the fifth rib; the lower border was palpable 3 cm. below the costal border. The spleen was felt running out from beneath the ribs in the anterior axillary line, downward just to the right of the umbilicus, then downward and backward to just above the anterior-superior spine and backward into the flank. The surface was smooth; the consistency was firm; the notch was palpable in the nipple line. The spleen was apparently somewhat tender. The epiphyses at the wrists were enlarged. The extremities were otherwise normal. There was a slight general enlargement of the lymph nodes.

Urine: pale, acid, 1010, no albumin or sugar. Blood: hemoglobin, 40%; red corpuscles, 4,000,000; white corpuscles, 18,750; small mononuclear, 34.4%; large mononuclear, 12.6%; polynuclear neutrophiles, 51%; eosinophiles, 0.2%; myelocytes, 1.8%. The red corpuscles showed marked variation in size, shape and staining reaction. There was no tendency to large forms, but a slight tendency to oval forms. Sixteen normoblasts and 9 megaloblasts were seen in counting 500 white corpuscles.

She was put on a stronger milk and beef juice, and was given maltine and iron and syrup of the iodide of iron. The temperature remained normal, she took her food fairly well and did not vomit. There was a tendency to constipation.

On June 16 the tip of the spleen only reached 3 cm. to the left of the umbilicus. The examination of the blood on this date was as follows: hemoglobin, 65%; red corpuscles, 5,132,000; white corpuscles, 18,580; small mononuclear, 23%; large mononuclear, 6%; polynuclear neutrophiles, 69%; eosinophiles, 1%; myelocytes, 1%. There was moderate variation in the size and shape of the red corpuscles with slight variation in their staining reaction. There was a slight tendency to large and oval forms. In counting 500 whites, microblast, 2 normoblasts and 10 megaloblasts were seen.

She had measles in the latter part of June. After that her improvement was even more rapid than before. The spleen was not palpable after Aug. 1.

The examination of the blood Aug. 16 was as follows:

Hemoglobin, 65%; red corpuscles, 5,175,000; white corpuscles, 17,000; small mononuclear, 48%; large mononuclear, 3%; polynuclear neutrophiles, 45%; eosinophiles, 4%. There was slight variation in the size and very little in the shape of the red corpuscles. There was none in their staining reaction. No nucleated forms were seen.

She was seen Nov. 29, 1902, eighteen months after her admission. She was then perfectly well in every way. The lower border of the liver was palpable 3 cm. below the costal border. The spleen was not palpable.

CASE XX. Gladys W., five months old, was admitted to the Infants' Hospital April 29, 1902. The father undoubtedly had syphilis. There had been no miscarriages. The first child was well. This was the second child. She was normal at birth and was breast-fed. She developed snuffles at six weeks. She began to be pale at two months, and at the same time a fine rash appeared on the skin. Since she was three months old she had vomited a good deal, at times had had diarrhea, and had lost weight steadily.

She was small and poorly nourished. The anterior fontanelle was level. The posterior fontanelle was not quite closed. The superficial veins of the scalp were enlarged. Snuffles were marked. There was a slight rosary. The heart and lungs were normal. The liver was palpable 5 cm. below the costal border. The spleen was palpable, running out from behind the ribs in the anterior axillary line, forward to the left parasternal line at the level of the umbilicus, and downward and backward to the anterior-superior spine, filling up the whole flank. The surface was smooth, the edge sharp, the notch indistinctly palpable at about the level of the umbilicus. The abdomen was large and tense. There was an umbilical and a right inguinal hernia. The palms and soles were desquamating. There was a moderate general enlargement of the lymph nodes.

Blood: hemoglobin, 55%; red corpuscles, 3,750,000; white corpuscles, 16,200; small mononuclear, 50%; large mononuclear, 6%; polynuclear neutrophiles, 39%; eosinophiles, 5%. There was very little variation in the size of the red corpuscles and none in their shape. There were no nucleated forms.

She improved rapidly on anti-syphilitic treatment, and was discharged May 12. Nothing is known as to the further history of her case.

CASE XXI. John C., seventeen months old, was admitted to the Infants' Hospital April 21, 1902. He was the first child. He was fed on the breast for five months and then was given strained rolled oats. He had vomited occasionally and had lost some weight. The history was very indefinite.

He was well developed and fairly nourished. His color was good. The fontanelle was closed. There was a slight rosary. The heart was normal. The lungs were normal. The lower border of the liver almost touched the anterior-superior spine, reached to within 2 cm. of the umbilicus and passed under the left costal border in the left nipple line. The spleen was palpable, running out from beneath the costal border in the anterior axillary line directly downward to the level of the anterior-superior spine and backward into the flank. The surface was smooth, the density increased, the edge sharp, the notch not palpable. The abdomen was large and lax. The epiphyses were considerably enlarged at the wrists and moderated at the ankles. The legs were slightly bowed. There was a slight general enlargement of the lymph nodes.

Urine: Pale, 1008, no albumin. Blood: Hemoglobin, 65%; red corpuscles, 3,720,000; white corpuscles, 10,700; small mononuclear, 30%; large mononuclear, 4%; polynuclear neutrophiles, 56%; eosinophiles, 1%. There was a little variation in the size and none in the shape of the red corpuscles. No nucleated forms were seen.

He was seen Nov. 29, 1902, seven months later. He was then a large fat, healthy-looking baby. The liver was palpable 3 cm. below the costal border. The spleen was not palpable. His color was exceptionally good.

CASE XXII. Stanley A., negro, fourteen months old, was admitted to the Infants' Hospital May 21, 1902. There had been no other children or miscarriages. He

was breast-fed up to six months and was then put on Mellin's Food. He had had no gastro-enteric disturbances. He had had a cough off and on for two months.

He was small and poorly nourished. The head was much flattened on top and the forehead prominent. The anterior fontanelle was 3 cm. in diameter. The bridge of the nose was flattened. There was marked snuffles. There was marked pallor of the mucous membranes. There was a slight rosary, and the sides of the chest were somewhat flattened. The heart was normal. The lungs were normal except for an occasional moist rale. He sat up, but feebly. The liver was palpable 3 cm. below the costal border in the nipple line. The spleen was felt running out from beneath the ribs just outside the left nipple line downward and forward to 2 cm. below and about 1 cm. outside the navel, then back into the deep abdomen. The anterior border, tip and a portion of the lower and external borders were easily made out. It then disappeared into the deep abdomen. The anterior edge was rather sharp, the surface smooth, the notch distinct. It was not tender. The whole spleen was easily movable. The abdomen was generally enlarged but lax. There was a slight enlargement of the epiphyses at the wrists. There were knock-knees. There was a moderate talipes valgus on both sides. There was a slight general enlargement of the lymph nodes. There were no ragjades and no fissures or mucous patches about the anus. There was pigmentation on the face and about the anus as if there had been an eruption at some time. The soles were dry and desquamating.

Urine: High, acid, 1022, no albumin. Blood: Hemoglobin, 50%; red corpuscles, 3,750,000; white corpuscles, 29,600; small mononuclear, 30%; large mononuclear, 18%; polynuclear neutrophiles, 48%; eosinophiles, 2%; myelocytes, 2%. There was marked variation in the size and shape of the red corpuscles, but no tendency to oval or large forms. There was a slight general polychromatophilia. In counting 200 white cells, 7 microblasts, 8 normoblasts and 12 macroblasts were seen. There was marked polychromatophilia of the nucleated forms. The most striking thing in the blood was the large number of large mononuclear cells with large, feebly staining nuclei and a small amount of feebly staining protoplasm.

The temperature at entrance was 101° F. It began to rise the next day without any apparent cause. The physical examination was entirely negative. The temperature reached 107° F. on May 24, and the child died that night.

ILLUSTRATIVE CASES OF SECONDARY ANEMIA IN INFANCY.

CASE XXIII. George T., eleven months old, was admitted to the Infants' Hospital March 6, 1902. He was premature, at seven months. He had always been fed on undiluted cows' milk. He had always cried a great deal, vomited after feeding, and had always been constipated. He had never gained.

He was poorly developed and nourished. There was marked pallor of the skin and mucous membranes. There was a slight rosary. The heart and lungs were normal. The liver was normal. The spleen was not palpable. The abdomen was negative. There was a slight enlargement of the epiphyses at the wrists and ankles. There was a moderate general enlargement of the lymph nodes.

Urine: normal, acid, no albumin. Blood: hemoglobin 25%; red corpuscles, 2,600,000; white corpuscles, 15,000; small mononuclear, 63%; large mononuclear, 3%; polynuclear neutrophiles, 33%; eosinophiles, 1%. There was marked variation in the size of the red corpuscles but none in their shape or staining reaction. No nucleated forms were seen.

He was seen Nov. 24, 1902, nearly eight months later. There has been no improvement in any way. The spleen was not palpable.

CASE XXIV. Joseph B., twenty-two months old, was seen July 22, 1897. His digestion had always been very feeble and he had always been pale. He had had bronchitis in the winter and more or less nasal discharge

since then. For two weeks he had been running a moderate temperature, and the pallor had increased.

He was well developed and nourished, but very pale. There was a slight rosary and a slight general enlargement of the lymph nodes. The physical examination was otherwise negative.

Blood: hemoglobin, 42%; red corpuscles, 4,560,000; white corpuscles, 29,720; small mononuclear, 45.5%; large mononuclear, 6%; polynuclear neutrophils, 47.5%; eosinophiles, 1. There was much variation in the size and shape of the red corpuscles. No nucleated forms were seen.

He evidently entirely recovered.

CASES OF ANEMIA AND SPLENIC TUMOR WITHOUT EXAMINATION OF THE BLOOD, BUT WITH RECOVERY.

CASE XXV. William F., eighteen months old, was seen in consultation with Dr. J. P. Torrey of Andover, July 29, 1899. He had always been very pale, but had been well in other ways.

He was well developed and nourished. Pallor was marked. The anterior fontanelle was closed. He had sixteen teeth. There was a slight rosary. The heart was normal. The liver was normal. The spleen reached nearly to the umbilicus. The surface was hard, the edge thin, the notch palpable. The abdomen was negative. The extremities were normal. The cervical lymph nodes were slightly enlarged, the others not.

He was treated with iron and arsenic. Dr. Torrey wrote Oct. 29, 1899, three months later, that the spleen was no longer palpable.

Dr. Torrey examined him again in December, 1902. The boy was then in good health, but still somewhat pale. The spleen was not enlarged.

CASE XXVI. Wolff S., thirteen months old, was admitted to the Infants' Hospital March 14, 1899. He had always been improperly fed and had always suffered from disturbances of digestion.

He was poorly developed and nourished. The fontanelle was 6 cm. in diameter. There was a marked rosary. The heart and lungs were normal. The liver was palpable almost as low as the umbilicus in the right nipple line. The spleen was palpable at the level of the umbilicus. The epiphyses at the wrists and ankles were enlarged. There was a moderate anterior bowing of the tibia. There was a moderate general enlargement of the lymph nodes.

He was seen Aug. 7, 1902, three and one-half years later. At that time he was perfectly well. The liver was normal. The spleen was not palpable. There was no enlargement of the lymph nodes.

CASE XXVII. Max S., twenty-two months old, was seen at the Out-Patient Department of the City Hospital in February, 1897. He had been very sick during the summer of 1896 with diarrhea. The abdomen had been distended, and Dr. Deering had found an enlarged spleen. He had had more or less disturbance of digestion since that time, and a few weeks before coming to the hospital had had a sharp attack of fermental diarrhea from which he was recovering.

He was well developed and nourished and moderately pale. There was a slight rosary but no other evidences of rickets. The liver was normal. The spleen was palpable about 5 cm. below the costal border. The blood was not examined at that time.

He was seen again in May, 1897, three months later. At that time he was in very good condition and of good color. The tip of the spleen was just palpable. The blood at that time showed hemoglobin, 105%; red corpuscles, 5,160,000; white corpuscles, 5,000; small mononuclear, 30%; large mononuclear, 1%; polynuclear neutrophils, 62%; eosinophiles, 7%. There was a very little variation, in the size of the red corpuscles but none in their shape. No nucleated forms were seen.

THE RELATION OF ENLARGEMENT OF THE LIVER TO THAT OF THE SPLEEN.

In estimating the size of the liver in infancy it

must be remembered that it is normally proportionately larger than in adult life. While under normal conditions it usually does not extend more than 2 or 3 cm., it may extend as much as 4 cm. below the costal border. Only six of the livers in this series were larger than this (11, 15, 16, 17, 20, 21.) Two (17, 20) of these cases had congenital syphilis. In general the largest livers were associated with the largest spleens. In three (18, 19, 22) of the five (18, 19, 20, 21, 22) cases, however, in which the spleen reached to the anterior superior spine, the liver was not enlarged. Enlargement of the liver was, therefore, evidently not dependent upon that of the spleen nor enlargement of the spleen on that of the liver.

THE RELATION OF ENLARGEMENT OF THE LYMPH NODES TO THAT OF THE SPLEEN AND LIVER.

There was a general enlargement of the lymph nodes in every case in which their condition was noted. The greatest enlargement was found in cases in which the spleen was much enlarged (14, 15), but they were moderately enlarged in a case in which the spleen was only slightly enlarged (4), and they were only slightly enlarged in three (19, 21, 22) of four cases (19, 20, 21, 22) in which the spleen was the largest. There was no evident relation between the size of the lymph nodes and that of the liver. They were much enlarged with both normal (14) and enlarged (15) livers, and slightly enlarged with both normal (2) and enlarged (21) livers. The enlargement of the lymph nodes could not have been due, therefore, to that of the spleen or liver. Enlargement of the lymph nodes is, moreover, almost invariably found in all conditions of malnutrition in infancy. Hence it must be regarded here, as elsewhere, merely as a manifestation of malnutrition.

THE RELATION OF THE NUMBER OF RED CORPUSCLES AND THE AMOUNT OF HEMOGLOBIN TO THE SIZE OF THE SPLEEN.

The number of red corpuscles bears no constant relation to the size of the spleen. This is evident if the cases are arranged according to the number of red corpuscles and compared with the arrangement according to the size of the spleen. The arrangement according to the number of red corpuscles, beginning with the largest number, is 13, 11, 8, 10, 5, 3, 16, 15, 17, 19, 22, 20, 21, 7, 12, 18, 2, 14, 4, 6, 1, 9. The two smallest counts were in two cases in which the enlargement of the spleen was slight (9, 1); the largest, 5,800,000, was in a case (13) in which the spleen reached to the umbilicus. In five cases (5, 10, 8, 11, 13) there were over five million red corpuscles, while in five others (3, 15, 16, 17, 19) there were over four million. The lowest count in the cases in which the spleen reached to the anterior-superior spine (18) was 3,556,000, while the lowest in those in which the spleen reached to the umbilicus (14) was 2,553,000.

There was no evident relation between the number of red corpuscles and the size of the liver.

The diminution in the amount of hemoglobin was always relatively greater than that in the number of red corpuscles. The hemoglobin, however, is

always relatively low in infancy, and a relatively great diminution in the amount of hemoglobin is characteristic of the anemias of infancy. The color index in these cases bears no relation to the size of the spleen or liver.

THE RELATION OF THE NUMBER OF WHITE CORPUSCLES TO THE SIZE OF THE SPLEEN.

The arrangement of the cases according to the number of white corpuscles, beginning with the minimum, is as follows: 6, 2, 14, 1, 21, 11, 18, 17, 13, 10, 8, 3, 20, 12, 5, 4, 7, 19, 9, 22, 15, 16. Accepting 14,000 as the normal limit of white corpuscles, there was no leucocytosis in eight (6, 2, 14, 1, 21, 11, 18, 17). Four of these cases (14, 17, 18, 21) were among those in which the spleen was largest. Of fourteen cases in which the number of white corpuscles was increased, the spleen was but little, or moderately, enlarged in seven (3, 4, 5, 7, 8, 9, 10), and much enlarged in seven (12, 13, 15, 16, 19, 20, 22). The largest leucocytosis (47,220) was in a case in which the spleen reached to the umbilicus (16) and the next largest (31,500) in another case in which the spleen reached to the umbilicus (15), but in one case in which the spleen reached to the umbilicus (14) there were only 8,200 white cells, and in the case with the next to the largest spleen there were only 10,700.

It is evident that there was no constant relation between the number of leucocytes and the size of the spleen. The largest spleens were sometimes unaccompanied by leucocytosis, and there was sometimes a marked leucocytosis when the spleen was only slightly enlarged. The largest leucocytoses were usually found, however, in connection with the largest spleens.

THE RELATION OF THE NUMBER OF WHITE CORPUSCLES TO THE SIZE OF THE LIVER.

There was no evident relation between the size of the liver and the number of white corpuscles. There were only 10,700 white cells in the case with the largest liver (21), while the two cases in which the leucocytosis was largest showed only a slight enlargement of the liver (15, 16). Leucocytosis was also marked in cases with normal-sized livers (9, 22).

THE RELATION OF THE NUMBER OF WHITE CORPUSCLES TO THE SIZE OF THE LYMPH NODES.

There was no evident relation between the size of the lymph nodes and the number of white corpuscles. In the two cases in which the enlargement of the lymph nodes was greatest (14, 15) there were 8,200 and 31,500 white corpuscles, respectively. There were, moreover, 47,220 white corpuscles in a case in which the enlargement was slight (16).

THE RELATION OF THE NUMBERS OF RED AND WHITE CORPUSCLES TO EACH OTHER.

The numbers of red and white cells have no constant relation to each other; for example, in one case (16) there were 4,200 white, and 1,736,000 red cells, and in another (2) 4,800 white and 3,288,000 red. In one case (16) with 4,408,000 red corpuscles there were 47,220 white, while in another (17) with 4,200,000 red corpuscles there were only 13,400.

THE RELATION OF THE MORPHOLOGICAL CHANGES IN THE RED CORPUSCLES TO THE OTHER SIGNS.

In a very general way the degree of the morphological changes varied with the number of red corpuscles, the more marked changes occurring in the cases with the smallest numbers of red corpuscles. There were many exceptions to this rule, however. The changes were, on the whole, more marked in the cases with leucocytosis.

There was no correspondence between the degree of the morphological changes and the size of the spleen. The morphological changes were most marked in four cases (1, 6, 7, 9,) in which the spleen was not much enlarged, and in four (12, 15, 19, 22) in which the spleen was much enlarged.

The morphological changes varied, therefore, rather with the number of red and white corpuscles than with the size of the spleen; that is, they formed a part of the pathological changes in the blood and were not connected with those in the spleen.

Certain peculiarities are worth noting. In some cases the morphological changes were marked while there was a comparatively slight diminution in the number of red cells. Nucleated cells were present in cases in which there was little or no diminution in the number of red corpuscles; for example, normoblasts with 5,158,000 red corpuscles (10), and megaloblasts with 4,340,000 (15) and 4,000,000 (19) red corpuscles. In several of the cases which recovered (12, 18, 19) large nucleated red corpuscles were very abundant. These changes are, of course, merely examples of the tendency of anemia in infancy to revert to the fetal type of blood.

There was no correspondence in the amount of the enlargement of the liver and of the spleen. There was no correspondence in the degree of enlargement of the lymph nodes and of the liver and spleen. There was no constant relation between the diminution in the number of red corpuscles and the size of the spleen and liver. There was no constant relation between the number of leucocytes and the size of the spleen and liver, although the largest leucocytoses were usually found in connection with the largest spleens. There was no constant relation between the number of leucocytes and the degree of enlargement of the lymph nodes. There was no constant relation between the number of red and white corpuscles. The morphological changes in the red corpuscles did not vary with the size of the spleen, but in a very general way, with many exceptions, with the number of red and white corpuscles, showing that they were a part of the pathological blood condition and not connected with the condition of the spleen. The degree of the morphological changes was in a general way a guide as to the severity of the anemia. Very marked changes did not necessarily point to a fatal outcome, however, as several cases (12, 18, 19) in which they were most marked recovered. They merely show the tendency of the blood in the anemias of infancy to revert to the fetal type. The hemoglobin was always relatively low, as it almost always is in the anemias of infancy. The condition of the blood in Cases 23 and 24, in which there was no enlargement of the spleen, shows that there is nothing characteristic about the blood

changes found in infancy in association with splenic tumor. The conclusion seems justified, therefore, that the enlargement of the spleen, liver and lymph nodes developed independently of each other, and that they were not directly connected, either as cause or effect, with the changes in the blood.

Granting that this conclusion is correct, the association of these conditions suggests that they are all the results of some common cause.

ETIOLOGY.

Rickets was present in all but two of the cases (6, 9). Neither of these had very large spleens, but they ranked first and third as regards the severity of the anemia. The rachitic changes were slight in eleven (1, 2, 3, 5, 7, 12, 14, 15, 17, 20, 21), moderate in six (4, 8, 11, 13, 18, 22), and marked in three (10, 16, 19). The enlargement of the spleen and changes in the blood were considerable in two (16, 19) of the three cases in which the rachitic changes were marked, but no greater than in other cases (15, 21) in which they were slight. It is evident, therefore, that the rickets was not the direct cause of these pathological conditions, but was itself a symptom of some common cause. Further evidence that rickets was not etiologically responsible for these conditions is the fact that 80% of the children under two years of age at the clinic from which these cases were taken show more or less marked signs of rickets, while these conditions are comparatively rare.

Disorders of the gastro-enteric tract were present in every case in which data were obtained. In two of those without data the food had been unsuitable. There was a history of improper food in all but four (2, 3, 13, 14) of the cases with data on this point. These cases were fed on the breast, and all had gastro-enteric disturbances. It is probable, therefore, that in these cases too the food, even if it was breast milk, was unsuitable. Diseases of the gastro-enteric tract, whether or not due to improper food, are not always followed by anemia and enlargement of the liver and spleen, and therefore cannot be the direct cause of these conditions. Disorders of the gastro-enteric tract, do, however, always cause disturbances of nutrition, and it is to these disturbances of nutrition that they probably owe their etiological importance.

Two (17, 20) of the cases had syphilis. It was in both associated with rickets, improper food and gastro-enteric disturbances. No especial importance can be attributed to it, therefore, as a general etiological factor. It undoubtedly acts chiefly by disturbing nutrition.

Prematurity and pertussis, each present in one case (7, 9), probably acted in the same way.

Disturbances of nutrition in infancy may produce various results. Rickets and scurvy are undoubtedly peculiar manifestations of disturbances of nutrition. In other instances disturbances of nutrition produce atrophy, anemia or enlargement of the lymph nodes, liver or spleen. Why disturbances of nutrition in one case cause rickets, in another atrophy and in another anemia or enlargement of the lymph nodes or spleen is not known. The fact that they do cause all these various conditions explains the peculiar combinations in which these conditions are found and their evident independence of each other.

CONCLUSIONS.

It seems justifiable to conclude, therefore, that when anemia, splenic tumor and enlargement of the liver or lymph nodes are found in association in infancy they are in no way dependent on each other, but are all manifestations of a common cause — disturbance of nutrition; that there is nothing characteristic about the blood changes found in association with enlargement of the spleen, as similar changes are found when there is no enlargement of the spleen; that the anemia is secondary rather than primary; that there is no justification for placing the cases of anemia in infancy associated with enlargement of the spleen or liver in a class by themselves and calling it "anemia infantum pseudo-leukenika," or "splenic anemia of infancy"; that these terms should be dropped from our nomenclature.

PROGNOSIS.

The ultimate fate of these cases is of some interest. Seven disappeared from view after a short time; two (12, 16) of these probably died; five (5, 7, 8, 17, 20) probably recovered; two (17, 20) of these were syphilitic.

Seven are known to have died; one (13) of meningitis, and six (1, 3, 6, 9, 15, 22) without complications. They died after three days, five days, one month, one month, two months and seven months. The blood changes were marked in all of these cases. They included most of the severest cases. The spleens were very large in three (13, 15, 22), but comparatively small in the others.

One (12) was doing well after eight months. Seven (4, 10, 11, 14, 18, 19, 21) were well after six months, seven months, seven months, 18 months, two and one-half years, six years, seven years. The blood changes were moderately severe in these cases. Nucleated reds were numerous in five, megaloblasts predominated in two. Nucleated red corpuscles and megaloblasts are, therefore, evidently not of so much importance in prognosis in infancy as in later life. Five of these cases (12, 14, 18, 19, 21) were among those with the largest spleens, and two (10, 11) of the others had considerably enlarged spleens. Two of the largest spleens were not palpable after seven and eight months (21, 12). Others were found absent after seven months (11), eighteen months (19), two and one-half years (4), and seven years (18). One (10) was just palpable after six years. In three cases in which the spleen was much enlarged, although the blood was not examined, it was not palpable after three months (25), five months (27) and three and one-half years (26). One (21) very large liver was of normal size after seven months, another (11) moderately enlarged, one was still slightly enlarged after seven months. The improvement in the blood condition during recovery is seen in Cases 19 and 27.

The prognosis in these cases depends, therefore, more on the condition of the blood than on the size of the spleen. Recovery may take place even when the changes in the blood are very severe. The size of the spleen has no influence on the prognosis. The largest spleens may return to the normal size in a few months.

THE REPORT OF THREE CASES IN WHICH EMBRYOS OF THE STRONGYLOIDES INTESTINALIS WERE FOUND IN THE STOOL.—AUTOPSY OF ONE CASE.

BY PHILIP KING BROWN, M.D., SAN FRANCISCO, CAL.

Two of the following three cases were patients in the wards of the Medical Department of the University of California in the service of Dr. Kerr. The cases are reported because of the interest in this subject aroused by the discovery of a case of the kind at the Johns Hopkins Hospital by Dr. Richard Strong, and two additional cases studied and reported in full with a history of the parasite and its pathological significance by Dr. William Thayer of Johns Hopkins. The subject has a further interest, for in addition to the fact that one of these patients was an American who probably contracted the trouble in this country, the two others were natives of Porto Rico, and were among a number of laborers who passed through this country on the way to the Hawaiian Islands, and one of them had been in the Hawaiian Islands and was returning. The commonness of the trouble in Porto Rico has been called attention to by the army medical corps. The absence of any serious symptoms even in the severest of my cases is a matter of some interest, but the extent to which the infection may spread in districts where the water supply is not the best suggests the need of considering this infection seriously. It is not at all certain that these parasites that bury their heads deep in the mucous membrane of the intestine, to which class the trichocephalus hominis also belongs, are as harmless as we have been led to believe. The finding of the strongyloides adult worms with the heads buried deep in the mucous membrane suggests the fact that they are true parasites of the host, and not a class that subsist upon the contents of the bowel. Complication of two of my cases with uncinariasis is interesting because of the supposed severity of the anemia which occurs with this disease. The cases are reported as follows:

CASE I.—V. M., aged eighteen. Porto Rico. Laborer. Entered City and County Hospital, Nov. 25, 1902.

Family history negative.

No alcohol. Smokes moderately. No genito-urinary history. Seven years ago in Porto Rico suffered from a fever from which he claims never to have recovered, but felt fairly well until taken with a chill a few days ago. Accompanying it were headache and general condition of prostration. Patient felt as though he must have the same fever he had in Porto Rico. He has no appetite. Pain in the right side of abdomen. No vomiting, bowels have been rather loose for some months but particularly in the last month.

Chest negative. Liver from the lower border of the fourth rib to 2 cm. below the costal margin. Spleen not enlarged. Tenderness all over the right abdomen on deep pressure not very severe except in the right mammary line below the border of the liver.

Blood examination: No plasmodia found; hemoglobin 75%; white corpuscles, 7,600; polynuclears, 67; large mononuclears, 9; small, 14; eosinophiles, 10%. Feces contained a number of larvae of the strongyloides intestinalis, ova of trichocephalus hominis, also some large oval eggs with a clear shell and a clear space inside the shell, the center being occupied by a granular mass or by what appears to be the divisions of this mass into from two to twenty cells. The character of the eggs is not definitely determined, but they are supposed to be uncinaria.

Patient discharged once from the hospital, but re-

turned four days later, feeling again very badly. Thymol in two doses, 2 gm. each, were given to remove the parasites if possible.

The result of the thymol was disappointing, for a search of the feces showed no adult uncinaria or strongyloides. Cultivation of the feces, however, enabled us to differentiate between the larvae of the strongyloides intestinalis and the uncinaria.

CASE II.—E. G., thirty years. Native of Porto Rico. Laborer. Complaints of vague pains throughout the body. No change in appetite. No diarrhea. No particular symptoms referable to stomach.

Leucocytes, 7,000; eosinophiles, 5%; hemoglobin, 95. Stools show large number of strongyloides larvae; trichocephalus eggs and eggs resembling uncinaria, from which, however, no typical larvae developed. He was a friend of case V. M., and a stool was obtained from him during one of his visits to the hospital.

CASE III.—J. P. W., age sixty-five. Pastry cook. Resident of San José, Cal. Born in Tennessee. Lived in California from 1851 to 1861, and continuously since 1868. Was in Mexico and South America in 1861, while serving on a United States warship. Got ashore on passes, and for a day or two only, about nine days in whole cruise. During Civil War he served in the army for two years, principally in Maryland and Virginia. Lived in Philadelphia three or four years just after that.

Had typhoid and malaria while a boy in Tennessee. Was very well in California except for "bilious headaches," which he has had from early boyhood. Constipated when young, more so now. Appetite generally very good. Nausea and vomiting with headaches. Never sick, except with present trouble, since he came to California. For six or eight months before this he had felt better than for many years. Bowels pretty regular. Two weeks ago had sudden nausea with vomiting. Nausea continued with less vomiting each day for four days. Vomitus was bitter and yellow, and it relieved him to get it up. No diarrhea, fever or chills. Cramps in various parts of the body when he moved. Relieved by moving about. This was only for first three days and was worse at night. Was conscious of some fever. No night sweats or cough. No history of jaundice. During bilious attacks he has had some pain in abdomen after he has vomited for a long time. Once or twice vomited a black material. No blood or coffee grounds. Never has had pains in limbs or fever before with bilious attacks.

Jan. 26, 1903, the blood showed the following condition: Red cells, 3,882,000; hemoglobin, 65%; white cells, 9,400; polymorphonuclears, 71½%; large lymphocytes, 12½; small lymphocytes, 9¾%; eosinophiles, 6½%. Urine.

On account of the eosinophilia, and because stools are being examined as a matter of routine, an examination was made in this case. The single dejection was copious, dark brown in color and formed. No mucus was apparent, and the general appearance was unsuggested. Particles of fecal matter removed indiscriminately from the mass showed dozens of embryos of the strongyloides intestinalis in every specimen, and often as many as ten or twenty in the field of a five objective Leitz. The embryos were practically all actively motile, and about the same stage of development. No adult worms were found and no eggs. Nor were they ever found, although searched for many hours on various occasions, frequently immediately after the passage of stools following drastic purging. Thymol administered in two 30 gr. doses followed by oil seemed to have no effect on the number of embryos nor did it long affect the motility of them. For some hours after the stools were passed most of the embryos were motionless, but later a good many of them regained their normal activity. Cultivation of the stools in a constant temperature oven at 37° resulted in the development of maturer stages of the larvae, but after three or four days they all died.

An attack of pneumonia occurred while the parasite was being studied, and the patient died. An autopsy was done at the earliest possible moment.

Autopsy of J. P. W., 18th Feb., 1903.

Patient died at 9 p.m., Feb. 17, of pneumonia of five days standing. Autopsy fifteen hours postmortem, rigor mortis present. No distension of the abdomen. No external conditions of note.

Left pleural cavity filled with a fibrinous clot, slightly adherent both to the lung and the chest wall, which was very much inflamed and rough. The clot peeled off rather easily, leaving both pleural surfaces very slightly roughened. The left lower lobe was solid, contained no air. Dark red on section. The left upper lobe extremely edematous. Frothy fluid flowing freely from the cut surfaces. Few adhesions at the left apex. Right lung presents almost similar condition, except that there was no consolidation of the lower lobe, although but small amount of air was to be forced from the cut surface. The diaphragmatic surface presented the same yellow clot that the left lung showed. In addition to this there was considerable quantity of purulent material well walled off, about 1½ oz. in all. This was broken into when the lung was separated from the diaphragm. There were firm adhesions between the pleural surfaces all over the anterior and axillary parts of the lung. Tubercular scar at the right apex.

Enlarged glands behind the aortic arch. Turbid fluid in the pericardium; small amount. Thick-walled left ventricle. Valves clear throughout. Muscle pale and brownish.

Abdominal cavity contained about 100 cc. of turbid yellowish fluid, and the right side of the abdomen particularly showed the intestines pretty well matted together by a purulent substance, and in the vicinity of the appendix were some old adhesions. The intestines were very red and the veins very much distended.

The mesenteric glands were not particularly enlarged.

The liver presented nothing abnormal on cut surface.

The gall bladder was distended with semi-fluid bile. The ducts were patent.

The spleen was double the natural size, and very soft. Readily torn in being moved.

Both kidneys were small, with quite adherent capsules, and on cut surface presented cloudy swelling of the cortex, and rather a pale appearance. There were a few pearl gray nodules scattered irregularly throughout the cortex about a pin head in size.

Pancreas apparently normal. Size of the stomach was normal, and externally presented no unusual signs. No evidence of any fresh infection from the appendix.

The diaphragmatic surface of the liver did not show extension of the process from the abscess of the pleura above.

The stomach and intestines were removed *en masse*, first having been tied off at intervals of about 2 feet and at the important anatomical points along the course, to facilitate the examination as to distribution of the parasites. The mucous membrane of the stomach was thickened, and an excessive quantity of adherent mucus lined it throughout. The reaction of the mucus was acid, as was also that of the upper part of the duodenum. No parasites or eggs were found anywhere in the stomach, but immediately below the pylorus, within ½ inch of the stomach, where the contents were still acid, were found the parent worms of the strongyloides intestinalis, large quantities of embryos and eggs, not alone in the intestinal contents, but deeply embedded beneath the coat of mucus which lined the entire gastro-intestinal tract. The eggs were found particularly abundant in the deeper layers, and often apparently embedded in the mucous lining, so that removing the mucus and later scraping the lining, gave the best specimens of eggs that were found at all. It was noted also that as far down as the ileocecal valve, parent worms, eggs and embryos were found closely adherent to the mucous membrane. As the examination proceeded from the duodenum, a greater number of embryos appeared to be found in the intestinal contents, and while the duodenum and jejunum showed everywhere apparently the same extent of distribution of parasites, below this point the embryos were found in greater numbers in the intestinal contents. A single field of a Leitz microscope, number four eyepiece, number six objective, showed from ten to forty or fifty of the embryos. Parent worms were found as low down as the beginning of the ascending colon, but no eggs were found in the colon, although they were found at the lower end of the ileum. Larvæ were found in the proximal end of the appendix, but none were found in the bile or the gall duct or pancreatic duct. In the upper part of the intestinal tract one to three parent worms were found

on every coverslip. Lower down it required often the search of two or three coverslips to show a single one.

An examination of sections removed from the duodenum and hardened in formalin showed an extensive disintegration of the structural layers of the mucous membrane due to postmortem change. There was no inflammatory process in the mucous layer at all, with the single exception of the appearance of a considerable number of eosinophiles immediately around certain of the worms which were buried deep down in the mucous membrane. Neither eggs nor worms were found in the muscularis mucosa, but both were found in considerable numbers in the crypts of Lieberkuhn, the parasites often projecting into the interstitial tissue, having apparently burrowed horizontally through the layers of cells. In the accompanying photographic illustrations, the relation of the eggs and parasites to the layers of mucous membrane are shown. The worms are not always straight, but appear in a number of cases to be curled up and occupying the Lieberkuhn crypts. The division of the nucleus of the eggs is shown in a few of the sections of eggs, but this division was not seen in any eggs found in the intestinal contents.

The adult parasites that were found were all of exactly the same type and represent what I take to be parthenogenetic mother worms. No adult males were found at any time. Nor were we able to cultivate them from the feces during life or from what was removed from the intestinal tract at autopsy. The direct transformation of the radiiform embryos to filariform larvæ was the only change noted, and in spite of various means employed, these larvæ generally died on the fourth or fifth day. This transformation seems to be apparently the rule, as Leichtenstern has pointed out. This observer studied a small number of cases through many years, and points out that other forms of development do occur, but not as constantly or regularly as the direct change. The whole subject of the method of development has been gone over so well and so interestingly in the article already mentioned by Dr. Thayer,¹ that I would refer any one interested in it and for illustrations of the eggs, embryos and larvæ to that article.

As regards the symptoms produced by this parasite, two of these cases were of no avail as pictures of the trouble, because of the complication with uncinaria infection. But it is notable that even in these cases the diarrhea was either absent or extremely slight. In the uncomplicated case there never was at any time any history of diarrhea, although the case was certainly a severe one. And there could scarcely be said to be a severe anemia. As Nourmand in 1877 described the disease, there appeared to be mild dyspeptic symptoms, loss of appetite, pasty, frequent stools, showing sometimes mucus and blood, and in extreme cases being choleraic in character. Nourmand calls attention to the absence of any severe anemia. Thayer and Strong's cases showed a chronic diarrhea constantly, but one was complicated by amebic dysentery. One of his cases also showed a marked secondary anemia, although the hemoglobin was 57%. The absence of eosinophilia was noted in one of his cases,

¹ Journ. Exp. Med., vol. 6, no. 1, November, 1901.

in which particular it differed from mine. The presence of the eosinophilia in some degree has been a strikingly constant symptom in every single case in which I have found intestinal parasites, and in no less than 10 or 12 cases where the trichocephalus homines alone appeared, the percentage of eosinophiles rarely fell below 5, although the total number of leucocytes was unaltered.

A CASE OF GUNSHOT WOUND OF THE STOMACH. OPERATION. RECOVERY.

BY HUGH WILLIAMS, M.D., BOSTON.

On the afternoon of August 30, 1902, I was called by Dr. Nason of Newburyport to see a case of gunshot wound of the abdomen.

The accident, as nearly as could be ascertained, had occurred at 12.30 P.M. The patient, a boy of sixteen, had been shot by a .38 Smith & Wesson revolver.

you approached this point. This was also the point of greatest pain. The whole abdomen was flat to percussion except over the gastric area, where there was diminished resonance.

The general condition of the patient was very good. There was but little shock, and no active hemorrhage, although sufficient time had elapsed since the accident for him to have bled considerably if any large vessel had been injured. His general condition, however, did not show any such active process.

I decided to open the abdomen at once. The patient was etherized by Dr. Nason, and an emergency preparation of the abdomen made. Dr. W. B. Odiorne and Dr. Day assisted at the operation. A probe passed into the wound entered the abdominal cavity at the median line, two inches above the umbilicus. An incision was then made in the median line from the ensiform cartilage to the umbilicus, and the abdomen opened. The

STRONGYLOIDES INTESTINALIS.—BROWN.

normal in appearance, as far as distension was concerned, but the lineæ transversæ and semilunares were exaggerated, as when a strong person is contracting his abdominal muscles for show. The wound of entrance of the bullet was seen one inch to the right of the umbilicus, and about half an inch below. The track of the bullet could be seen for one inch or more, its course being at an angle from right to left, and in a direction from below, upward and inward. Except on pressure, there was no hemorrhage from the wound, which had been covered with a moist corrosive dressing. The abdomen had been shaved, and everything made ready for operation. Palpation showed general but moderate rigidity of the abdominal muscles. There was marked tenderness in the epigastrium, in the median line about two inches above the umbilicus, but there was no tenderness except as

pressure was applied between the stomach and the transverse colon, and opened the lesser peritoneal cavity. No gas, blood or gastric contents were found here, and the posterior stomach wall felt intact. The region of the foramen of Winslow and the remainder of the anterior surface of the stomach were then explored, but no hemorrhage could be found. No wound of exit from the stomach could be discovered, nor any evidence of one.

Though the patient was standing the operation remarkably well, I did not deem it safe to leave the stomach so distended with food, as my line of sutures would be three inches long, and vomiting would almost inevitably follow the operation if the stomach was not previously emptied. By removing some of the contents, I should also be able to explore the inside of the stomach. I therefore enlarged the opening in the stomach throughout its wounded surface, making the wound one and three-fourths

Left pleural cavity filled with a fibrinous clot, slightly adherent both to the lung and the chest wall, which was very much inflamed and rough. The clot peeled off rather easily, leaving both pleural surfaces very slightly roughened. The left lower lobe was solid, contained no air. Dark red on section. The left upper lobe extremely edematous. Frothy fluid flowing freely from the cut surfaces. Few adhesions at the left apex. Right lung presents almost similar condition, except that there was no consolidation of the lower lobe, although but small amount of air was to be forced from the cut surface. The diaphragmatic surface presented the same yellow clot that the left lung showed. In addition to this there was considerable quantity of purulent material well walled off, about $1\frac{1}{2}$ oz. in all. This was broken into when the lung was separated from the diaphragm. There were firm adhesions between the pleural surfaces all over the anterior and axillary parts of the lung. Tubercular scar at the right apex.

Enlarged glands behind the aortic arch. Turbid fluid in the pericardium; small amount. Thick-walled left ventricle. Valves clear throughout. Muscle pale and brownish.

Abdominal cavity contained about 100 cc. of turbid

on every coverslip. Lower down it required often the search of two or three coverslips to show a single one.

An examination of sections removed from the duodenum and hardened in formalin showed an extensive disintegration of the structural layers of the mucous membrane due to postmortem change. There was no inflammatory process in the mucous layer at all, with the single exception of the appearance of a considerable number of eosinophiles immediately around certain of the worms which were buried deep down in the mucous membrane. Neither eggs nor worms were found in the muscularis mucosa, but both were found in considerable numbers in the crypts of Lieberkuhn, the parasites often projecting into the interstitial tissue, having apparently burrowed horizontally through the layers of cells. In the accompanying photographic illustrations, the relation of the eggs and parasites to the layers of mucous membrane are shown. The worms are not always straight, but appear in

eggs were found particularly abundant in the deeper layers, and often apparently embedded in the mucous lining, so that removing the mucus and later scraping the lining, gave the best specimens of eggs that were found at all. It was noted also that as far down as the ileocecal valve, parent worms, eggs and embryos were found closely adherent to the mucous membrane. As the examination proceeded from the duodenum, a greater number of embryos appeared to be found in the intestinal contents, and while the duodenum and jejunum showed everywhere apparently the same extent of distribution of parasites, below this point the embryos were found in greater numbers in the intestinal contents. A single field of a Leitz microscope, number four eyepiece, number six objective, showed from ten to forty or fifty of the embryos. Parent worms were found as low down as the beginning of the ascending colon, but no eggs were found in the colon, although they were found at the lower end of the ileum. Larvæ were found in the proximal end of the appendix, but none were found in the bile or the gall duct or pancreatic duct. In the upper part of the intestinal tract one to three parent worms were found

with anemias infection. But it is notable that even in these cases the diarrhea was either absent or extremely slight. In the uncomplicated case there never was at any time any history of diarrhea, although the case was certainly a severe one. And there could scarcely be said to be a severe anemia. As Nourmand in 1877 described the disease, there appeared to be mild dyspeptic symptoms, loss of appetite, pasty, frequent stools, showing sometimes mucus and blood, and in extreme cases being choleraic in character. Nourmand calls attention to the absence of any severe anemia. Thayer and Strong's cases showed a chronic diarrhea constantly, but one was complicated by amebic dysentery. One of his cases also showed a marked secondary anemia, although the hemoglobin was 57%. The absence of eosinophilia was noted in one of his cases,

¹ Journ. Exp. Med., vol. 6, no. 1, November, 1901.

in which particular it differed from mine. The presence of the eosinophilia in some degree has been a strikingly constant symptom in every single case in which I have found intestinal parasites, and in no less than 10 or 12 cases where the trichocephalus homines alone appeared, the percentage of eosinophiles rarely fell below 5, although the total number of leucocytes was unaltered.

A CASE OF GUNSHOT WOUND OF THE STOMACH. OPERATION. RECOVERY.

BY HUGH WILLIAMS, M.D., BOSTON.

On the afternoon of August 30, 1902, I was called by Dr. Nason of Newburyport to see a case of gunshot wound of the abdomen.

The accident, as nearly as could be ascertained, had occurred at 12.30 P.M. The patient, a boy of sixteen, had been shooting on Plum Island with a friend of about the same age. At the time of the accident he was in a reclining position, and his friend, who was seven or eight feet away, in front and a little to his right, was unloading a 32-caliber revolver. Whether the cartridge exploded within the pistol, or was dropped upon some hard object, could not be determined, as the boys told different stories. The bullet from the exploded cartridge entered the abdomen, passing through cotton shirt and undershirt. The mid-day meal — consisting of apples, watermelon, and herring with pickles — had been eaten at noon, or about half an hour before the accident. The boy was taken in an ambulance from Plum Island to the Anna Jaques Hospital, a distance of four miles. He had not vomited; but had complained of severe pain in the epigastrium, and had been given morphia gr. 1-8. He was unable to urinate, and had been catheterized of eight ounces of normal urine. The bowels had moved thoroughly in the morning.

When I saw the patient — four hours after the injury — he was lying quietly on his back on the operating table, with the knees out straight. He was perfectly calm, — not at all disturbed either by his own condition or by his surroundings. He was strong, healthy, well-developed. The pulse was full, a little bounding, but of excellent quality, and the rate varied between 115 and 120. The temperature was 100°. The abdomen was practically normal in appearance, as far as distension was concerned, but the lineæ transversæ and semilunares were exaggerated, as when a strong person is contracting his abdominal muscles for show. The wound of entrance of the bullet was seen one inch to the right of the umbilicus, and about half an inch below. The track of the bullet could be seen for one inch or more, its course being at an angle from right to left, and in a direction from below, upward and inward. Except on pressure, there was no hemorrhage from the wound, which had been covered with a moist corrosive dressing. The abdomen had been shaved, and everything made ready for operation. Palpation showed general but moderate rigidity of the abdominal muscles. There was marked tenderness in the epigastrium, in the median line about two inches above the umbilicus, but there was no tenderness except as

you approached this point. This was also the point of greatest pain. The whole abdomen was flat to percussion except over the gastric area, where there was diminished resonance.

The general condition of the patient was very good. There was but little shock, and no active hemorrhage, although sufficient time had elapsed since the accident for him to have bled considerably if any large vessel had been injured. His general condition, however, did not show any such active process.

I decided to open the abdomen at once. The patient was etherized by Dr. Nason, and an emergency preparation of the abdomen made. Dr. W. B. Odiorne and Dr. Day assisted at the operation. A probe passed into the wound entered the abdominal cavity at the median line, two inches above the umbilicus. An incision was then made in the median line from the ensiform cartilage to the umbilicus, and the abdomen opened. The moment the peritoneum was incised, gas began to escape in small amounts, and the stomach near the pylorus presented in the wound. No fluid, intestinal or gastric contents or blood could be seen. As the direction of the bullet was upward to the left, I walled off the stomach with gauze, and delivered its anterior surface toward the fundus. This almost immediately brought into view in the anterior stomach wall a wound which, being in a glancing direction almost parallel to the wall of the stomach, showed that the bullet had lacerated the visceral peritoneum in the first inch of its course only. The ball had then penetrated deeper, and one-half inch further on it had turned directly backwards, making a ragged punctured wound through the stomach wall. This point was, approximately, two inches above the lower border of that organ and four inches from the pylorus. From this wound was escaping a little gas and a small quantity of liquid of the consistency of thick soup, though there was no evidence of any fluid having escaped before the manipulations began.

The stomach was found distended with a semi-solid material from the last meal. It was, in fact, so full that handling forced from the wound some of its contents. The wound was then partly closed with silk Lembert sutures, and well walled off with gauze, and a gauze pad was held by Dr. Odiorne over the opening. I then made an incision in the great omentum, between the stomach and the transverse colon, and opened the lesser peritoneal cavity. No gas, blood or gastric contents were found here, and the posterior stomach wall felt intact. The region of the foramen of Winslow and the remainder of the anterior surface of the stomach were then explored, but no hemorrhage could be found. No wound of exit from the stomach could be discovered, nor any evidence of one.

Though the patient was standing the operation remarkably well, I did not deem it safe to leave the stomach so distended with food, as my line of sutures would be three inches long, and vomiting would almost inevitably follow the operation if the stomach was not previously emptied. By removing some of the contents, I should also be able to explore the inside of the stomach. I therefore enlarged the opening in the stomach throughout its wounded surface, making the wound one and three-fourths

inches in length. The stomach was then rapidly emptied. The contents consisted of about three pints of odorless, semi-solid material, much like piccalilli. The internal surface was then carefully explored, and still no evidence of a wound of exit could be found, nor was the bullet found, though very nearly all the contents were removed, only a small amount remaining in the fundus. During the process of emptying the stomach, there was very little soiling of the field of operation, and what little fluid escaped seemed to be well taken care of by the walling-off gauze. The wound in the stomach was then closed by three layers of interrupted Lembert silk sutures. The whole field was flushed out with salt solution, which came back as clean as it went in. The lower part of the abdomen was inspected, and examined with the hand. There was no blood in either flank or elsewhere. The intestines were as collapsed as if the patient had been under a forty-eight hour operation. A small gauze wick was passed into the lesser peritoneal cavity and another to the line of sutures in the stomach, this point being directly under the wound of the abdominal wall, which was then partly closed with interrupted through and through silkworm gut sutures. The external wound of entrance was excised and drained with gauze. The patient stood the operation very well, his pulse at the close being 130, and in quality very little weaker than at the beginning.

It was suggested after the operation that the bullet might have made a hole in the stomach as it glanced over it, and then gone on, entering the diaphragm, and perhaps lodging in the pleural cavity. It could not have entered and injured the lung to any extent, for there was no coughing of blood, and I do not think that it merely glanced over the surface of the stomach, for exploration and examination with the hand of the area above the stomach, including the liver and the diaphragm, failed to show anything abnormal. Then, too, it seemed probable that the bullet entered the stomach, for the nature of the wound in the stomach showed that the first portion was grazed and bruised, while at the upper end there was a ragged, sharply defined wound, with no evidence of a bruise or contusion of the peritoneum beyond this point. What changed the direction of the bullet it is impossible to say. It might have been that the bullet had already begun to change its course after passing through the abdominal wall, as very little will change the course of a slug-shaped bullet; or the change of direction might have been owing to the fact that the stomach was distended and elastic, and that the bullet was nearly spent at the time.

Whether or not it was wise to empty the stomach at the time of operation, was a question that had to be decided at once. It certainly added to the danger of infection, and it also lengthened the operation; but it seemed best at the time, considering the amount of distension of the stomach and the large area to be sutured, which was not increased to any extent. The duration of the operation from the starting of the ether was forty-five minutes, and very little ether was required.

For the first two days after the operation the temperature varied between 100° and 102°, and the pulse between 90 and 120; but after this both fell

to normal, and did not give any further cause for alarm. The wick to the lesser peritoneal cavity was removed on the fifth day, and that to the line of stomach sutures on the seventh day. There was no sign of infection from either sinus or from the wound of entrance in the abdominal wall. Nothing was given by mouth for one week. The patient was fed by rectal enemata, which were well retained; and it was stated by the nurse that he had a well-formed, normal movement each day. The thirst was controlled by washing the mouth and giving a sufficient amount of salt solution by rectum. Only one dose of morphine was given during convalescence. The wounds were all healed without infection at the end of two weeks. At the end of three weeks, the patient was up, was on a light diet and feeling perfectly well. His stools were all examined, but the bullet was not found. Dr. Nason has reported this patient well at the end of five months.

The interesting questions in this case seem to me to be those of drainage and of emptying the stomach through the abdominal wound.

The boy might have recovered if the wound in the stomach had simply been sewed up, the abdominal cavity thoroughly flushed out with salt solution, and the external wound entirely closed. Patients have been known to recover under this treatment. On the other hand, it has sometimes proved fatal; for example, the case which is still fresh in every one's mind. The dangers of infection were, that the bullet was probably septic after it had passed through two layers of clothing and through the skin, and that the stomach wall was broken by it, and was leaking liquids and gas. It seems to me impossible to cleanse a wound of this kind so that it can safely be closed. There is also always the danger of a wounded pancreas, which if not drained means practically certain death. Drainage, therefore, gives the patient the benefit of a doubt which, if disregarded, may cost him his life.

If an abdominal wound of this kind is closed, especially after irrigation, the bacteria will be so disseminated that a general infection will be given every chance to assert itself. There are similar cases in which drainage seems to me to be imperative; for example, those in which it is sometimes asserted that the abdomen may be closed without drainage, such as an appendicitis, either during the ulcerative stage, when it is believed that the bacteria have not had time to get through the wall of the appendix to the peritoneum, or when the patient has passed through an acute attack and an operation is performed as soon as the temperature is normal. In both of these conditions the abdomen has sometimes been closed at the time of the operation and the patient has recovered; but I think every surgeon has seen or has heard of patients who have died of a general peritonitis when treated in this way who might have recovered if a temporary drain had been employed.

Emptying the stomach in this case was a fortunate procedure, as the subsequent history shows, — indeed, it seems to me to be the most important factor in his recovery; for there was no vomiting at any time after the operation. This could hardly have been expected if the stomach had been left distended with food. Moreover, this great advantage was gained, that the stomach sutures were put to

no unusual strain; therefore healing of the approximated surfaces was not interfered with; and the drainage took care of any local infection from leaking, either from the sutured surface or from the posterior surface of the stomach, where there might possibly have been a wound that was overlooked at the time of operation.

Clinical Department.

A CASE OF MULTIPLE FIBROMATA (FIBROMA MOLLUSCUM) AND SEROUS CYST OF NECK.

BY DAVID D. SCANNELL, M.D., BOSTON.

THE individual, the pictures of whom form the basis for this contribution, was observed in Matanzas, Cuba. On sight, he presented nothing more

than the cystic tumor of neck, striking enough in itself to be well worth a photograph. Removal of his upper clothing, in order to bring out better the

details of the cyst, disclosed the other and more striking growths.

In the presence of the illustrations, I feel that much in the way of explanation is unnecessary, excepting perhaps the following concerning the individual himself: Age seventy-two; Cuban by birth; laborer; good health always; tumor on neck of twenty years' duration, very slow, progressive enlargement, unattended by any discomfort except

that resulting from mechanical interference. The exact duration of the fibromata could not be learned; he thought the small ones on the trunk and extremities dated from childhood; the large ones pendent from the arm had developed during the last ten years.

The cyst of the neck was tense, firmly fixed, fluctuant, and slightly translucent. The fibromata were all soft and gelatinous, the large, pendulous ones giving the suggestion of containing "boiled vermicelli." There was no apparent tendency on the part of the large ones to ulcerate. The skin, especially on the trunk, was considerably thickened. In the right back, it was markedly lax, so that it could easily be lifted away from the subcutaneous tissues as much as three or four inches.

Medical Progress.

RECENT PROGRESS IN SURGERY.

BY HERBERT L. BURRELL, M.D., AND HAYWARD W. CUSHING, M.D., BOSTON.

(Continued from No. 21, page 558.)

THE TECHNIQUE OF GASTRIC LAVAGE.

Dr. C. Neck²¹ reports the following observation relating to gastric lavage, stating that the point in its technique noted has been used by him to advantage in clinical work, especially when it was necessary to entirely empty the stomach previous to operative work on that viscus. He claims that if the operator wishes to be sure that the stomach is entirely empty, the lavage should be finished with

²¹ Centbl. f. Chir., 1902, vol. xxix, p. 1337.

the patient in a position with the pelvis raised (Steile Beckenhochlagerung), and the stomach tube should be slowly withdrawn. When the lavage is performed, as is customary, with the patient recumbent or sitting, a certain amount of stomach contents remains, due, apparently, to the fact that the cardiac orifice is not the most dependent point of the cavity to be emptied and that at times the eye of the wash tube is not situated at that point. By placing the patient in a position which makes the cardiac orifice the lowest point, and slowly withdrawing the tube, these obstacles to the complete emptying of the cavity have been removed. This observation Dr. Neck claims to have verified by experimental work on the cadaver and clinical experience.

EXPERIMENTAL CONTRIBUTION TO THE KNOWLEDGE OF THE PATHOLOGY OF GASTRIC ULCER.

The writer, R. Dalla Vedova,²² was led to an investigation of the cause of gastric ulceration by the statement of Durante that the classical appearance of this lesion first occurred when all the tissues of the stomach wall were predisposed to it by a marked disturbance of its innervation. The investigation consisted in destroying in dogs the vagi, the celiac plexus and the splanchnic nerve (section or alcohol injection), and then studying the resulting changes in the stomach mucous membrane. In a large number of the animals marked voracity occurred during the first few days following the operation. In thirty-three of forty-five cases the results could be tabulated, showing that with injury to the vagus—six cases—no change followed in the mucous membrane and no ulcer occurred. In twelve cases of the celiac plexus, the mucous membrane was altered in five (41%), and in two ulceration followed. In fifteen cases of the splanchnic nerve the mucous membrane was affected nine times (60%), and ulceration was noted in six cases. Limited examination of the urine (postmortem) showed only occasionally a trace of albumen, never sugar or acetone. As regards the amount of hydrochloric acid in the gastric secretion, Vedova believes that at times it is increased. The anatomical changes in the mucous membrane occurred most frequently in the region of the pylorus, where either single or multiple (even to number of fifty) they appear in the form of necrosis, hemorrhages, erosions, ulcers and cicatrices. Usually, also, the stomach wall is covered with a coffee-brown, tea-like mucus. The vicinity of the ulcer which enters the stomach wall deeply was free from infiltration reaction, but in the immediate vicinity of the ulcerated surface a small-celled infiltration occurred. The vessels in the vicinity were, as a rule, thrombotic. Vedova concludes from his experiments that one can produce, by injury to the celiac plexus or splanchnic nerves in dogs, changes in the gastric wall which stand in close relationship to the gastric ulcer in man.

THE PREDISPOSING AND EXCITING CAUSES OF SUDDEN ATTACKS OF APPENDICITIS.

Riedel,²³ Jena, gives a very valuable paper on this subject.

The author sets out by promulgating certain theses, and, as these form the groundwork of his Arbeit, they will be quoted almost *in extenso*.

(1) A healthy appendix, free from foreign bodies, practically never becomes by itself the seat of that disease known as appendicitis.

(2) An otherwise healthy appendix may take part in a cecal catarrh, but this in no way alters the microscopic structure of the organ. Whether a disease analogous to appendicitis may originate in this manner or not is unsettled, but apparently it may not.

(3) Appendicitis is almost always an insidious disease, which develops with scarcely a symptom. Like cholecystitis, it is usually discovered when an acute inflammatory process attacks the organ already suffering from chronic disease.

(4) A sharp or angular foreign body may enter and perforate a healthy appendix, and rapidly produce a disease which remotely resembles suppurative appendicitis. Rounded foreign bodies (for example, enteroliths) can also, in time, perforate the organ directly; but, as a rule, they may by their presence slowly prepare the way for an acute inflammatory attack, and this latter produces the perforation.

(5) There are two predisposing causes for a sudden attack of appendicitis:

(a) An enterolith forms in a healthy appendix, and occasions more or less circumscribed secondary disease; (b) The appendix becomes the seat of an entirely characteristic primary disease.

(6) This characteristic primary disease is appendicitis granulosa.

(7) Enteroliths usually form in healthy appendices, but, exceptionally, they may arise in those affected by appendicitis granulosa or tuberculosa.

(8) Strictures or stenoses of the appendix may be formed,—sometimes as a result of the presence of enteroliths, which are later evacuated into the cecum, or sometimes as a result of appendicitis granulosa (rarer).

(9) An acute attack of non-suppurative appendicitis is only occasionally traceable to an enterolith present in an almost healthy appendix. The predisposing cause for such an attack is usually appendicitis granulosa, or stricture or stenosis.

(10) An acute attack of suppurative or gangrenous appendicitis is more common in an appendix prepared for it by the presence of an enterolith than in one the seat of appendicitis granulosa, or of stricture or stenosis.

(11) In the former, as a rule, the character of the attack is more severe, progressive, and leads more quickly to gangrene. Acute gangrene of the appendix may occur on the basis of appendicitis granulosa and of stricture and stenosis.

(12) As a rule, the acute attack in cases of stricture and stenosis tends to run a mild course. Gangrene is less common in cases of stricture than in those of appendicitis granulosa. When stenosis is present, gangrene is scarcely possible.

(13) In appendicitis granulosa the acute attack is apparently often precipitated by hemorrhage into the granulation tissue. The effused blood presses the tissues apart, elevates and injures the epithelium, and bacteria gain access to the small lymphatics of the chronically inflamed organ. The attack is very much like erysipelas of the skin.

²² Archiv. f. Verdaunungskrankheiten, Bd. viii, Hft. 3.

²³ Arch. f. klin. Chir., Annals of Surgery, June, 1902.

(14) Marked general symptoms follow the lymphatic infection. When the lymphatics of an abdominal organ which is the seat of chronic disease become infected, local peritoneal irritation often occasions vomiting.

(15) As erysipelas is sometimes mild, sometimes severe, so acute lymphangitis in the chronically inflamed appendix is sometimes mild, sometimes severe. Mild lymphangitis gives rise to non-suppurative, severe to suppurative inflammation of the appendix, and the latter often leads to gangrene, because the enterolith which prepared the soil is putrid.

(16) An acute attack in an appendix predisposed to it by any of the above-mentioned means (erosion by enterolith, appendicitis granulosa, stricture, stenosis) may lead to abscess formation without perforation of the appendix. To such abscesses alone belongs the name peri-appendicular.

(17) Occasionally, though rarely, non-suppurative appendicitis gives rise to peri-appendicular abscess remote from the appendix itself.

(18) Abscesses, especially those due to appendicitis granulosa, are comparatively frequently resorbed, because they are hardly, if at all, putrid.

(19) Appendicitis granulosa has a distinct tendency towards spontaneous recovery through obliteration of the appendix. The obliteration may ensue slowly and insidiously or rapidly after an acute attack.

(20) Strictures and stenoses rarely recover spontaneously, especially rarely if they have been caused by enteroliths.

(21) The worst enemy of the patient is the eroding enterolith; it impresses on any attack the imprint of malignancy. The acute attack in cases of appendicitis granulosa is comparatively harmless. The putridity of an enterolith leads to the formation of putrid pus.

(22) The old and frequently neglected idea that enteroliths are principally to blame for bad terminations to appendicular inflammation must be held correct. Scarcely one third of such cases run their course; all the rest are severe. Exceptionally a cure results from the escape of the stone into the cecum, generally, however, on its departure it leaves behind a stricture or stenosis of the appendix.

It will be seen that Riedel considers that acute appendicitis is due to two causes; namely, the presence of eroding enteroliths and of chronic or granulating appendicitis.

A NEW USE FOR THE APPENDIX.

A very ingenious idea²⁴ is advanced for the use of that supposedly superfluous human appendix. Dr. Weir shows the advisability of making an artificial anus at the cecum, or in the upper portion of the colon, in those persistent and intractable cases of colitis which frequently prove fatal under medical treatment. He had done one operation of this kind in which he made a Kader-Gibson fistula, by placing a medium-sized catheter in a small opening in the cecum and applying two or three rows of purse-string sutures so as to invert the adjacent peritoneal coat. When he was about to do another case the

appendix presented itself so easily that he at once made use of it in his operation. He sewed the tip of the appendix into the wound, and then, opening the end, ran a small catheter through its lumen into the cecum. If one were sure that it was patent it would be unnecessary to open the appendix until adhesions formed. Irrigations were subsequently carried on through this organ, and the case made a good recovery. The danger of shock and peritonitis is very much lessened by this means, and the subsequent treatment in closing or removing the appendix is comparatively simple, and entails very little danger.

SUTURE OF THE LIVER.

After we pass Glisson's capsule, according to Dr. R. C. Coffey,²⁵ the softer structures of the liver have no more power to retain sutures to control and counteract blood pressure than so much mush. He thinks it of no use to apply sutures directly to the liver tissue for this purpose, and employs a mattress suture where all the pressure comes on Glisson's capsule at three or four points. The pressure is all the time toward the center of the incision, and obliterates all the space at the bottom. Two sutures are used, one being applicable to an incision which does not penetrate the liver entirely, and the other is applicable to wounds in which the liver is severed through and through. One he calls the Y-suture, the other the X-suture. The Y-suture is placed as follows: "A round curved needle, at least four inches long, armed with catgut or silk, is passed through the catgut support to the bottom of the incision, comes out on the other side, passes through another catgut support, re-enters through the support of the same side, goes back parallel to the other stitch and comes out through the support from which we started, making a quilt suture. A suture is then passed from the opposite side of the liver, either straight through or indirectly, as may be convenient, includes the two threads at the bottom of the cut in its loop, comes out on the bottom of the liver and again both ends passing through a single catgut weave are tied in the form of a quilt suture, thus drawing the other suture well into the bottom of the cut. The first suture is now tied, and any amount of pressure can be used, for the line of pressure is not against the suture, but is on the catgut supports. Thus the bottom of the wound is brought in absolute apposition, and any amount of pressure desired may be used. This may not bring the surface of the liver in as close contact as is desired; therefore a second quilt suture is passed through the edges of the support, nearest the wound, simply taking in the capsule. In this way the tissues are absolutely brought into contact, and as much pressure can be brought to bear in closing a wound of the liver as in any other part of the body. In closing a wound of the liver which extends entirely through its substance, a modification must be used. Instead of the single suture which goes into the bottom of the liver, a second quilt stitch is passed through both sides on the bottom, the same as the Y-suture above, interlocking the two sutures to the center of the wound. In this way the pressure is brought to bear in a very effect-

²⁴ R. F. Weir, *Med. Rec.*, Aug. 9, 1902; *Med. News*, Sept. 27, 1902, p. 602.

²⁵ *Med. News*, Aug. 30; *Journ. Amer. Med. Ass'n*, Sept. 13, 1902, p. 655.

ual manner." The cuts which illustrate the article give a better idea of the suture than the description, and the reader is referred to the original. Coffey says, as far as he knows, this method is entirely new, but he is conducting experiments on living animals to find the amount of catgut that will be absorbed. The points which are original are the use of the catgut weave for a support and the indirect or angular pressure made by a countertraction suture. The needle should be round, full-curved and fully four inches long. The one with which the counter-stitch is made may be a simple darning-needle, or any kind of a long straight needle.

(To be continued.)

Reports of Societies.

SIXTH MEETING OF THE CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS, HELD IN WASHINGTON, MAY 12 AND 13, 1903.

The president, DR. W. W. KEEN, was in the chair, and made an announcement with reference to the Major Reed memorial.

SESSION OF MAY 12.

SYMPOSIUM ON THE PANCREAS AND PANCREATIC DISEASES.

DR. E. L. OPIE of Baltimore read a paper on THE ANATOMY AND HISTOLOGY OF THE PANCREAS.

PROF. R. H. CHITTENDEN of New Haven then read a paper on

THE PHYSIOLOGY AND PHYSIOLOGICAL CHEMISTRY OF THE PANCREAS,

in which he referred to the many abnormalities that occur when the pancreas has been extirpated. Bodies, more or less toxic, are formed, and he believed that the cells of the pancreas had several more peculiarities of composition than one realized. He referred to the synthetic action of the pancreatic ferments upon glucose, and claimed that diet had much to do with the formation of enzymes. He believed also that the pancreatic juices were very much modified by food, and that there were many deviations from the ordinary metabolic processes of the body when the pancreas was extirpated.

DR. SIMON FLENNER of Philadelphia read a paper on

THE ETIOLOGY AND PATHOLOGICAL ANATOMY OF THE PANCREAS,

in which he referred to the relationship existing between inflammations and degenerations of the pancreas and diabetes. Commenting upon the production experimentally of hemorrhagic pancreatitis, he stated that certain forms of injury had been quite successful along this line. The nearest approach in the artificial production of hemorrhagic pancreatitis to that in man had been made by injections of natural gastric juice into the duct of Santorini, inflammatory symptoms appearing with great rapidity. Demonstrable, necrotic lesions appeared in the pancreatic cells in from four to six hours; but it is doubtful, in his opinion, whether the natural gastric juice of man ever gets into the pancreas and produces hemorrhagic pancreatitis. He did not

believe that gangrenous pancreatitis is of itself a disease, but believed it to be a secondary condition grafted upon a hemorrhagic pancreatitis. He divided suppurative pancreatitis into two forms—first, where the abscesses are small and localized, and, second, where they are large and diffuse. As regards spots of fat necrosis, they are frequently surrounded by a zone of hemorrhage; and their relation to the pancreas has long been suspected; they probably depend upon the presence of pancreatic juice. He considered that fat necrosis occurs, not only where the pancreas is in a state of acute inflammation, but also in cases of chronic inflammation.

DR. REGINALD H. FITZ of Boston read a paper on

THE SYMPTOMATOLOGY AND DIAGNOSIS OF PANCREATIC DISEASES,

in which he stated it had been known for centuries that diabetes may be associated with disease of the pancreas. In his opinion, disturbances due to pancreatic abnormalities usually indicated extensive interference with the function of the organ. He reported 29 cases of steatorrhea in which jaundice was present in 12 cases and absent in 17. He believed that there is less splitting of fat in pancreatic disease, and advises increasing the quantity of fat in persons suffering from this disease. The trouble, as he sees it, is to know just what the limitations are for this diet, and considers that a very important point to ascertain in this disease is the ability of patients to digest muscle fiber. The power of the pancreas to prepare food for assimilation should be ascertained by giving such foods as call for pancreatic activity. He referred briefly to the chemical tests for pentose, and also to the symptoms which are most important in the diagnosis of pancreatic disease.

Prof. Von Mikulicz-Radecki of Breslau read a paper on

INJURIES AND INFLAMMATORY PROCESSES OF THE PANCREAS,

and laid considerable stress upon the topographical relations of this organ. He mentioned two methods of exposing the pancreas—first, trans-peritoneally, and, secondly, retro-peritoneally. He believed that operations upon the pancreas were more dangerous than those upon any other abdominal organ, due to the fact that the general condition of the patient is usually so low. He collected 80 cases of operations, of which 41 died. Of the 80, 37 were drained. In operating he prefers to make the incision in the median line, and showed by statistics that all cases of pancreatic injuries not operated upon died, while of those operated upon many recovered. He urged early operation in these cases, claiming that far better results were secured than by waiting until abscesses formed. He believed that most cases die in the acute stage, and that the sub-acute is most favorable for operation. He mentioned four points in favor of early operation, but believed that the operation in all cases should begin as an exploratory incision.

DR. ROSWELL PARK of Buffalo read a paper on

TUMORS, CYSTS, ETC., OF THE PANCREAS, and approved of Dr. Robson's six divisions of pancre-

atic disease. He mentioned two cases of obstruction of the pancreas by lumbricoid worms, and stated that he believed hydatid cysts of the pancreas were extremely rare. He believed also that injury has more to do with pseudo-cysts than with the true pancreatic cyst, the symptoms of the latter being mainly those of pressure. Fat in the stools and glycosuria in these cases are very suggestive. Differential diagnosis of pancreatic cysts must be made from at least thirteen different kinds of cysts. The place of the incision depends upon where the tumor presents. Referring to drainage, he believed that this was often a life-saving remedy, and should be done posteriorly. In some cases he had observed that the discharge from the fistula increased when the patient became excited. He believed that cancer was most common at the head of the organ, and spoke of some which attained a great size. He considered that medicinal treatment must be symptomatic, but claimed to have gotten good results from operating, reporting 8 recoveries out of 16 cases. He referred briefly to tuberculosis and syphilis of the pancreas, and advised operation when in doubt.

DR. CHARLES G. STOCKTON of Buffalo discussed these papers, and stated that the question of diabetes in association with pancreatitis did not seem to be by any means settled, as there still seemed some reason for believing that diabetes may exist without ascertainable disease of the pancreas. One point upon which he laid considerable stress was polyuria. In his experience there are many cases in which there is relatively a large amount of sugar without corresponding increase in the quantity of urine, while in other cases there will be considerable urine with very little sugar. He mentioned a case which has been operated upon for a cyst of the pancreas in which glycosuria appeared a short time afterward. A year later this was considerably increased, and a few years afterward developed into a distinct diabetes. He mentioned that physiologists have found that the secretion of the stomach acts as a normal stimulant to the secretion of pancreatic juice, and that if the stomach secretion is diminished the secretion of the pancreas will also be, but clinically this is not the case. Where there is a disturbance of gastric juice, the intestinal digestion will be disturbed to some extent. He concluded by asking for a little delay in accepting the classification which had been suggested by Dr. Robson, although it had been favored by Professor Mikulicz and Dr. Park.

DR. HERBERT U. WILLIAMS agreed very largely with what Dr. Stockton had said, and commented upon the fact that in some respects our knowledge of pancreatitis and fat necrosis is very unique. He insisted upon the importance of fat necrosis in diagnosis, and considered that this information was easily obtained by the use of the microscope. He attached considerable importance to this information, and urged the wide circulation of its value. He dwelt briefly upon the experiments of Dr. Wells, and in referring to hemorrhagic pancreatitis mentioned the fact that it was long ago suggested that the action of the pancreatic juice upon the blood vessels might account for the hemorrhage in at least some cases. He made reference to his recent experience in endeavoring to prepare Kaiserling preparations from two specimens. His

results were extremely poor, and the color did not materialize, which in his opinion may possibly have been due to the action of the pancreatic juice. He agreed with Dr. Flexner as to the causation of acute pancreatitis, and added traumatism to the list of causes, as well as catarrh extending from the duodenum or the bile ducts. He mentioned that one often finds areas of fat necrosis at autopsy, and that sometimes these areas are associated with areas of hemorrhage.

DR. MAURICE H. RICHARDSON of Boston, continuing the discussion, said that acute lesions of the pancreas are very unusual. In seven thousand laparotomies at the Massachusetts General Hospital but six cases have been operated upon for acute pancreatic lesions; all fatal. The disease is as fatal, even though operated upon early, as it ever was, though death ensues later. In Dr. Richardson's two acute cases death followed after four weeks' drainage, the pancreas sloughing and escaping piecemeal. The lesion seems essentially fatal in infections apparently total. Patients surviving long enough for well-defined and protected abscesses have a better chance. Three hospital cases have survived. In several laparotomies Dr. Richardson has seen throughout the abdomen evidence of old healed, disseminated, fat necrosis without abnormalities in the pancreas. In operative wounds of the pancreas no bad results had followed. These wounds accompanied resection of the pylorus and operations involving the pancreas, but the number was small. The aseptic lesions of the pancreas have apparently a small mortality after operation. Five patients with cysts have all survived drainage, and one infant recovered from total extirpation of a large cyst supposed to be pancreatic. In the other cysts there was discharge of pancreatic fluid for years.

Cancer of the pancreas has been the indirect cause of death in many explorations and cholecystotomies for jaundice. Patients with jaundice and cholelithiasis associated with benign enlargements of the pancreas have, after removal of gallstones and drainage through the gall bladder, wholly and permanently recovered. By far the larger number of operations affecting the pancreas have been of this kind in Dr. Richardson's experience. In none of these cases was there any evidence, except by palpation of pancreatic disease, for all have recovered. To this condition the perhaps unjustified term "Chronic Pancreatitis" has been used. For the successful surgical treatment of acute pancreatic affections, if successful treatment is ever possible, much more must be known of the very earliest symptoms of these affections.

DR. B. S. A. MOYNIHAN of England agreed with most of what the previous speakers had said, and claimed to have operated on fifteen cases of chronic pancreatitis, of which all recovered. One of the cases was particularly interesting on account of the marked polyuria, amounting to 80 or 90 oz. daily, no sugar, and more than half of the gland was affected. He drained the gall bladder for some time, and then did a cholecyst-enterostomy. The patient progressed satisfactorily, but five months ago he developed glycosuria, and is now dying of diabetes. The second case was also very interesting, and was one in which the diagnosis had been made of chronic pancreatitis, and in which a

calculus was found in the pancreatic duct. On opening the abdomen he removed the stone, which was found to be composed of carbonate of lime. He believed that this was the first occasion in which pancreatic stone was diagnosed and found on operation. He admitted having had a small amount of experience with acute pancreatitis, and had only been able to find seven or eight cases, two of which were associated with cholelithiasis. One recovered without operation, but the other died.

PHILADELPHIA ACADEMY OF SURGERY.

STATED meeting, May 11, 1903, 8 P.M. DR. RICHARD H. HARTE, President, in the chair.

DR. WILLIAM J. MAYO, Rochester, Minn., read a paper entitled,

A REVIEW OF THREE HUNDRED AND THREE OPERATIONS UPON THE STOMACH AND FIRST PORTION OF THE DUODENUM.

Two hundred and eighty-six of these were taken from the records of St. Mary's Hospital, Rochester, Minn., and 17 from the Minnesota State Hospital for the Insane at Rochester and St. Peter. The average age of the patients was forty-two years, 42% being males and 58% females. There were 26 cases of duodenal ulcer with two deaths. Lesions in the first portion of the duodenum cannot be easily differentiated from lesions in the stomach which are due to the same causes. He divided lesions in the first portion of the duodenum into two groups — first, those caused by ulcer, and, second, those associated with gall-bladder disease. Of the ulcers limited to the duodenum, there was 1 acute perforating, 2 chronic perforating, 5 active and 3 cicatricial contractions with obstructive symptoms. Two deaths occurred, one from pneumonia and the other from exhaustion following gastro-enterostomy. Several of the cases could not be distinguished from gallstones until the operation, which was begun for that purpose, and which condition was frequently associated with it. In three cases the gall bladder was completely separated functionally from the bile tract; in four cases there were crippling adhesions to the gall bladder, but without stone or cholecystitis, requiring dissection to loosen. The differentiating features in these cases were good appetite, delayed pain, general absence of vomiting, and only in one case, and in that on only one occasion, was there hematemesis. The author expressed the opinion that surgical disease of the duodenum was much more frequent than has been supposed.

DISEASES OF THE STOMACH.

He divided these into two classes:

(1) Gastric ulcer and associated causes of serious disturbance. (2) Cancer of the stomach.

Out of the 303 cases reported in this paper 277 involved the stomach, with 28 deaths, or 10.1%; 168 of these cases were in the benign group, with 11 deaths. These cases included all the non-malignant obstructions or conditions calling for operation for gastric pain, with or without acute exacerbation. In the majority of the cases the perverted stomach secretions seemed to be the most important cause, which is shown by the almost constant association of excessive secretion with gastric

ulcer. Also in that part of the duodenum not protected by alkaline juices the same ulcers have also occurred after jejunostomy has been performed for the purpose of drainage. Drainage to relieve the excessive amount of secretion and thus produce healing of the ulcer is of great importance.

The following classification of gastric ulcer was made:

(1) Round ulcer, (a) acute; (b) chronic. It has the definite feature that there is but little thickening about the base.

(2) Mucous erosions — a condition which must be accepted with caution.

(3) Chronic ulcer with thickened base, and usually irregular in form.

(4) Benign obstruction without regard to cause.

The last two classes are the ones which most frequently call for operation; chronic ulcer is usually found in adults and more frequently in females. Spasm of the pylorus was thought to be one of the most important causes of the retention of excessive gastric secretion.

There were 109 cases of cancer of the stomach, with 17 deaths, or 15.6%. Late diagnosis and cachexia make the report of this group rather discouraging; most of the operations were of a palliative character. Early exploratory incision in suspected cases was recommended, and all the vascular and lymphatic connections with the diseased area should be removed. He then gave a full description of the method he employed in doing the operation. The period without recurrence after the operation has been varied, one case having gone two years and another three years and six months. He then discussed the three chief methods of improving stomach drainage; that is, pyloroplasty, gastro-enterostomy and gastro-duodenostomy.

DR. ALBERT VANDER VEER, Albany, N. Y., referred to the difficulty of diagnosing conditions in the lower third of the stomach and the upper third of the duodenum, referring to two cases in which he had thought that he was going to deal with a case of gastric ulcer, in which operation proved it to be duodenal ulcer. In cases where all the symptoms seemed to point very strongly to an ulcer in the stomach and none was revealed upon opening the organ, he believed it could sometimes be discovered by lifting out the organ and holding it up to the light. The difficulty of differentiating between carcinoma and ulcer when the growth occurred in the posterior wall of the stomach was commented upon and gastro-enterostomy thought to be the preferable operation for such conditions. He felt that many of the cases were left too long solely under the treatment of the medical man, and recommended exploratory operation when the clinical history and examination of the patient do not reveal clearly the conditions present. If possible, the complete operation should be done, but if the condition of the patient is such as to contraindicate this, much relief can be obtained by a gastro-enterostomy. In regard to shortening of the ligaments for the treatment of gastropexia, while he had had very little experience with this method, he felt that better results would be obtained by gastro-enterostomy with the establishment of good drainage. In regard to the pyloroplastic operation, he stated that he had in some instances gotten very

good results and in other instances the symptoms recurred, which he thought was probably due to the fact that the operation was too high up, and attributed Dr. Finney's success with this method to the fact that he made the outlet lower down.

DR. B. G. A. MOYNIHAN, Leeds, England, felt that the operation of pyloroplasty could be practically abandoned, he having done the operation three times, and in only one of the three cases did it prove satisfactory, in the third case a gastro-enterostomy being performed three or four months after the original operation. He did not feel that the operation was in any particular as satisfactory as the operation of gastro-enterostomy, stating that he had operated upon seventy-five cases by the latter method with only one death. He said that he had not used the Murphy button in the last sixty-five cases, as he believed the simple suture was preferable; but stated that in the employment of the Murphy button in the first of his cases, he had noticed that it destroyed a considerable portion of the mucous membrane around the union which he considered of very great importance, and which he had been doing in all his operations. By the method which he has employed the section of the stomach and the section of the jejunum where the anastomosis is to be made are each grasped in a pair of forceps and brought outside of the abdomen, and the continuous suture applied. In regard to malignant disease of the stomach he believed that the infection took place principally through the lymphatic system, and in the operation therefore he believed that first the greater curvature and then the lesser curvature should be removed. In regard to duodenal ulcer he believed that there were but very few cases in which this was a primary condition, but that in the majority of cases there had been a precedent gastric ulcer. Gastric ulcer is so frequently multiple that he did not believe excision to be practicable, as future trouble may result from a remaining undiscovered ulcer, and searching for the ulcer materially lengthens the operation of gastro-enterostomy.

DR. J. B. MURPHY, Chicago, referred to the fact that the great majority of all cases of carcinoma occur in the pyloric end of the stomach, and as the first set of glands to become involved by gravity are the lymphatic glands, any operation which is expected to produce permanent results must look to the removal of these glands, early operation being imperative. He further referred to the fact that about 10% of all cases of gastric carcinoma occurred in the cardiac end of the stomach, and are practically unamenable to treatment. He observed that the surgeon usually sees the cases of gastric disease in the following numerical order: (1) gastric carcinoma, (2) gastric ulcer, (3) pyloric stenosis, and (4) pyloric retention. As the gastric carcinoma is usually a sequence of the other conditions, he felt that in order to obtain the best results by operative treatment, the order in which these cases were seen should be the reverse. He believed that in order for the operation of pylorotomy to attain the best possible results, it was necessary that it should be done early. He referred to the fact that cases of gastropexia are treated erroneously by the medical man by washing out the stomach and reducing the amount of food, on the

theory that the condition is due to a weakening of the wall of the stomach, whereas, as has been definitely demonstrated by Dr. Mayo, it is due to a mechanical condition at the pylorus. He felt that the all-important factor in the operation was to secure permanent drainage of the most dependent portion of the stomach, and that the only operation which had been used a sufficient length of time to justify the statement that it was the best was gastro-enterostomy. He felt that if pyloroplasty was going to be of benefit to the patient it must be done early, in order to avoid ulceration and changes in the gastric secretions, which are apt to lead on to malignant disease. He also expressed the opinion that so soon as it became demonstrated to the physician that surgical operations were safe and afforded great relief, the cases would be sent to the surgeon much earlier.

DR. J. M. T. FINNEY, Baltimore, Md., confined his remarks to the consideration of pyloric stenosis of benign origin, and believed that the main question was thorough drainage, and any method that would produce this result he felt would be satisfactory. He referred to the fact that the advocates of gastro-enterostomy were far in excess of those who recommended pyloroplasty at the present time, which he believed to be due largely to the fact that the operation had not been properly performed. He felt that much better results could be obtained by the conjunctive work of the physician and surgeon in these cases, not necessarily with a view to immediate operation, but for the purpose of ascertaining the exact conditions present. He advocated early exploratory operation under cocaine. He felt that pyloroplasty was preferable to gastro-jejunostomy, from the fact that it makes the pylorus in a more normal position. The mortality in pylorotomy was too high to justify its employment, except in cases of pyloric cancer. He stated that he had employed the method as described by Hartman in eight cases of pyloric cancer, all of which made good recoveries and lived varying lengths of time. Owing to the nature of the growth, however, and the necessary involvement of the lymphatic structures, he felt that it was practically impossible to eradicate entirely the cancerous growth, and that recurrence would take place in a great many instances, for which reason he felt that the method advocated by Dr. Mayo of direct anastomosis of the lower end of the stomach to the duodenum would probably produce the best results. He thought that the operation of gastro-enterostomy had not been followed in all cases by the results claimed for it by some of the previous speakers, among the untoward effects frequently noted being the vicious circle and symptoms of pyloric obstruction, due to the fact that the outlet was made too high up in the stomach.

(The remarks of PROF. J.-v.-MIKULICZ-RADECKI, Breslau, Germany, were made in German, and were not reported.)

DR. J. CHALMERS D'ACOSTA commended the academy on their good fortune in having had the opportunity of listening to such great workers in this line as Drs. Mayo, Vander Veer, Moynihan, Murphy, Finney and Mikulicz-Radecki, and his appreciation of their courtesy in having participated in the papers and the discussions.

THE BOSTON
Medical and Surgical Journal

THURSDAY, MAY 28, 1903.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal, should be addressed to the undersigned.

Remittance should be made by money-order, draft or registered letter, payable to

THE OLD CORNER BOOK STORE (INCORPORATED),
 283 WASHINGTON STREET, BOSTON, MASS

THE ASSOCIATION OF MILITARY SURGEONS OF
 THE UNITED STATES.

THE recent highly successful meeting of this Association in Boston has drawn attention to the fact that the medical officer, regular or volunteer, must be a man of many parts and of broad learning, for he not only has to do with the care of the sick, with proper records of cases for the guidance of the government in the examination of pension claims, and with the healthful transportation of troops over long distances, but, as has been shown in the last few years, he must be capable of controlling epidemic disease among the populations temporarily subjected to military control during the continuance of war and the subsequent periods of reconstruction. He has had to meet promptly and satisfactorily the necessity of vaccinating nearly a million people in Porto Rico, the abolition of endemic yellow fever in the island of Cuba, and to attempt the control of cholera among the semi-hostile millions of the Philippines.

Nor has the demand for administrative capacity been confined to matters of sanitation. Within five years, in America, the Philippines, and South Africa, he has more than once been compelled to organize in a few days, in more or less inaccessible places, hospitals containing from five to seven hundred beds, and thenceforth to provide all the supplies necessary for their maintenance.

He has been called upon for scientific work also, and has responded promptly by his work on the etiology of yellow fever, thereby conferring a blessing upon the world which will outlive all memory of the Spanish War.

With such a broad field of labor it is not strange that the most animated discussion of this meeting

should have occurred upon the question of the education of the medical officer. The report of the Committee on the Army Medical School practically recommended that the education of the medical officer should be entirely assumed by the government, in much the same manner as is the education of line officers at West Point.

It was pointed out in the discussion that the necessary absence in this country of large, permanent military hospitals would make such a medical education exceedingly defective, and the present system of appointing medically qualified applicants and continuing the army medical school as a post-graduate school, analogous to the artillery school at Fortress Monroe and the cavalry school at Fort Riley, was more generally approved. Several gentlemen of the regular establishment recommended that this school be opened to medical officers of the militia, who should have transportation, commutation for quarters, and a certain amount of pay during their attendance. It is rather improbable, however, that any considerable number of gentlemen could be induced to abandon their private practice for five or six months of instruction in Washington.

Nevertheless, in time of war it is unavoidable that large numbers of young medical men should be called in to assist the army medical men in their duties, and it would seem that more attention to the duties of a medical officer should be introduced into the curricula of our medical schools. Could not army medical officers be detailed to give courses at the large medical schools of the country? Such details would give the military surgeons so detailed a year at a medical center, where they could do a large amount of post-graduate study in the hospitals, and continually send back into army work men fresh from the stimulating atmosphere of the great teaching centers.

The importance of the Association of Military Surgeons of the United States in bringing together the surgeons of the Army, Navy, Public Health and Marine Hospital Service, and the militia of the various states, has been fully recognized by the national government. It has been incorporated by Act of Congress, and for the last two years the national government has invited the nations of the world to send representatives from their military services to its meetings. This invitation has been promptly accepted, and medical officers have been sent from the English, Russian, French, Italian, Mexican, Japanese and Canadian medical services. The knowledge gained and the acquaintances thus formed by the medical officers of all the nations of the civilized world cannot but tend to ameliorate the sufferings occasioned by future wars.

THE INTERNATIONAL CONGRESS OF MEDICINE.

THE Fourteenth International Congress of Medicine has taken place at Madrid. Several considerations are suggested by the news which has reached us of this congress. In the first place, it is apparent that it has served as an object lesson of the necessity of careful preliminary arrangements and foresight in meeting the inevitable contingencies which must arise when a large number of people are to be accommodated. So far as we can learn, those who had the arrangements in charge fell lamentably short of their duties. It appears that a great amount of confusion regarding transportation met the foreign visitors, and that when they finally reached their goal, it was only with the greatest difficulty that they could find rest and lodging after their journey.

The confusion was worse confounded by the fact that the congress met at a most inopportune date. In the first place, the Easter holidays, when it is customary for large numbers of people to go to the larger towns, were scarcely at an end; many travelers, apart from those concerned in the congress, were returning to Madrid; the congress met at a time when general elections were about to take place throughout Spain, and finally, more members attended the congress than had been anticipated. All this naturally led to the inevitable result that hotels were overcrowded, and accommodations were at a premium. It is, however, hardly necessary to enter into the unfortunate details of mismanagement which have apparently marred this international congress. It must be remembered that various nationalities of varying tastes and habits were brought together in a Spanish city, to the customs of which no doubt many of them were utter strangers. Bull fighting on Sunday and the worship of the matador among other things, seem to have offended the good taste of the English visitors, and to have distracted their attention from the serious work of the meeting.

The scientific side of the congress, divided into the usual sections, brought forth many contributions of excellence, though none apparently of great scientific significance. There were also difficulties here. It was, for example, a matter of difficulty to find particular sections in the very large library and museum in which the meetings were held. According to the special correspondent of the *Lancet*, "Three sections met in what might be described as in the basement among exhibits of animals, elephants, crocodiles, tigers, crystals, minerals and assorted butterflies." Many chairs were provided, but there were no tables reserved for the press, and journalists were obliged to write on

their knees. Another difficulty was that in several instances it was impossible to reach one section without walking through rooms in which other sections met. There were pictures in abundance, many of them of great worth, and the museum collections were also of interest, but these again were matters apart from the business of the congress.

Most of the communications were given in Spanish, the natural consequence of which was that the work of many sections was carried on largely in the presence of empty chairs. English readers, for example, were naturally not encouraged to read their papers before an audience composed of Spaniards. These are hindrances naturally inherent in an international congress. At the best the difficulties to be overcome are manifold, and it is clear that only by the most careful arrangement can confusion be avoided. A further discouragement was that the weather during the time of the congress was exceptionally bad, interfering with the out-of-door program to an extreme degree. The formal ceremonies were somewhat characteristic of the country in which they were held, and were not conducted in the manner to which the more staid Anglo-Saxon is accustomed. In general, it must be said that this congress has suffered from various causes, some of which were clearly avoidable, and some of which were not. It will apparently not go down to posterity as a success in the same sense as the congress held three years ago in Paris was regarded.

 PRINCIPLES OF MEDICAL ETHICS.

AT its recent session, held in New Orleans, the American Medical Association took an important step in promulgating a document on the principles of medical ethics. As is generally known, the so-called Code of Ethics of the American Medical Association, first adopted in 1847, has in the supervening years led to a very considerable degree of misunderstanding, through the attempt to enforce its rulings upon members of the profession. The revision which has now taken place apparently places the entire matter upon a satisfactory basis, by changing the name from Code of Ethics to Principles of Medical Ethics, and thereby relieving the document of the somewhat unfortunate implications to which it had been subject during the last half century. The history which has led up to this ultimate revision it is certainly not necessary to relate; the fact only is now of importance that a document has been framed which, so far as one may see, can in no way give offence, and which should on the other hand prove a guide of positive value to practitioners of medicine.

We have read with care the full text of the report made before the House of Delegates, and find in it nothing to criticise. The physician's relations to the community and to his brother practitioners are given in detail, and there are certainly few points which have not been wisely touched upon by the committee in charge of the revision. To many readers it will appear that very much that is stated is well known and generally accepted by reputable physicians everywhere; at the same time, for the benefit of the uninitiated, and for men about beginning their medical practice, it is well that a brief, definite and straightforward statement should be made of the exact duties of a physician and of precisely what the profession at large will demand of him in his technical work. This the report before us seems to supply, and we should certainly commend its careful reading to physicians, whether young or widely experienced. The committee, composed of Drs. E. Eliot Harris, T. J. Happel, W. H. Welch and Joseph D. Bryant, submits to the President and members of the House of Delegates the following statement of their work in formulating the revised principles:

Your committee has given extended and careful thought to the proposed revision of the code of medical ethics referred to it for consideration. As you will note on caption of report, the word "code" has been eliminated, and the expression "The principles of medical ethics of the American Medical Association" adopted as adequately descriptive. In reference to this change it is proper to say that such action on its part is based on the idea that the American Medical Association may be conceived to occupy some such relation to the constituent state associations as the United States through its Constitution holds to the several states. The committee, for this reason, regards it as wiser to formulate the principles of medical ethics without definite reference to code or penalties, thus leaving the respective states, etc., to form such code and establish such penalties as they may regard to be fitting and proper for regulating the professional conduct of their members; provided, of course, that in so doing there be no infringement of the established ethical principles of the association. The committee regards as wise and well intended to facilitate the business of the parent organization and promote its harmony this course, which leaves to the state association large discretionary powers concerning membership and other admittedly state affairs.

Your committee has retained to a large extent the phraseology of the existing code, while aiming at condensation of expression and a better understanding of some of its statements.

The report of the committee has been reached unanimously without discussion or distrust on the part of its members, each aiming to formulate a result based on principle alone, and without regard to any past or present disagreements or misunderstandings whatsoever.

Such being the case, the committee invites your candid and unprejudiced attention and action to the results of its labor, feeling that at least some good has been accomplished.

THE VITAL STATISTICS OF THE UNITED STATES.

THE United States, as a whole, cannot be said to have an organized system of vital statistics such as is to be found in the older countries of Europe. The only attempts at collecting the vital statistics of the country at large are those which have been made in connection with the work of the United States census, during the past three or four decades. Several of the older states, however, have introduced systems of registration, beginning with that of Massachusetts in 1842.

The authorities of the Census Office have recently entered upon a commendable plan for promoting the work of registration of vital statistics throughout the country; and while the New England States, as a rule, have now adopted methods of registration which are fairly complete, there is abundant room for improvement in certain directions, which are indicated in the publications recently issued by the Census Office at Washington.

These publications consist of several circulars upon the following topics:

Legislative Requirements for Registration of Vital Statistics, including resolutions of Congress and the American Public Health Association, and a specimen form of an adequate law.

Practical Registration Methods. Use and treatment of the Standard Certificate of Death to secure the best results. Information for registrars.

Relation of Physicians to Mortality Statistics, with special reference to the statement of causes of death, and other details essential to accuracy and uniformity.

Medical Education in Vital Statistics, suggesting to Medical Colleges a special course of instruction for students upon registration and statistics.

Manual of the International Classification of Causes of Death; designed for use of officials compiling statistics.

The specimen form of law presented prohibits the removal or burial of any corpse without authority of a properly issued permit, based upon a complete and satisfactory certificate or return of the death; specifies the facts to be stated to make the return complete and satisfactory; imposes the obligation upon physicians, undertakers and others to make proper returns in every case; makes it the duty of the registrar issuing the permit to see that each return meets the requirements of the law, and also makes it the duty of the state registrar to see that the local registrars discharge their duties in a proper manner.

The circular to registrars explains the use, importance and necessity of the various details concerning each death required by the Standard Certificate; points out certain distinctions to be observed, and posts them concerning many indefinite or unsatisfactory terms used by physicians in stating causes of death.

The circular to physicians also describes the details required by the Standard Certificate; gives the titles of the International Classification, with explanatory notes showing the significance of various terms to the titles under which they are compiled, and a list of indefinite and unsatisfactory terms very frequently used by them

in reporting deaths, with a statement of the reasons why such statements are unsatisfactory.

The Circular to Medical Colleges suggests a plan of instruction of medical students in the purposes and necessity of registration,—their duties and obligations to the profession and the public,—and the relation and value of their certificates to vital statistics.

The Manual explains the International Classification as adopted by the Census Office, with an alphabetical "Index," showing to which title each one of many thousands of terms is referred. These are again grouped under each title, to show exactly what each includes.

Several special points treated in these circulars appear to us worthy of special mention as appealing to our New England population. *First*, The necessity of adopting the Standard Certificate of Death throughout the Union. Thus far, the only New England State which has adopted this form is Vermont. The custom of sending bodies from one state to another for burial, the facilities afforded for obtaining general information as to the causes of death in different states, demand the use of uniform methods in these states. *Second*, The circular of information for physicians should be widely distributed among the medical profession, and should be carefully used by every one who is called upon to sign burial certificates. The valuable list of indefinite terms published in this list has been carefully compiled from the experience of the Census Office, and is a very useful aid to the physician when he is in doubt as to the proper use of terms in signing death certificates. Very much of the uncertainty which arises in regard to the value of the published information as to the mortality from such causes of death as heart disease, cancer, diphtheria and tuberculosis is the result of the careless use of indefinite and unmeaning terms in signing death certificates. *Third*, The necessity of thorough instruction in vital statistics as an essential part of the medical curriculum. Such a course should include a general review of the origin and development of the modern system of boards of health and the basis of their operations; the utility and application of reports of disease, especially of infectious diseases; the registration of data of births and deaths, and its importance both to individuals and to the general public; the relation of vital statistics to sociological questions, to the advancement of medical science and of public hygiene, and all other matters germane to a thorough knowledge of the subject.

This subject is one of great importance to boards of health, both local and general, since, according to one of our foremost sanitary authorities, "The registration of vital statistics is the firm basis on which the whole structure of sanitary science and practice must rest. In order to learn the laws of

disease, to devise remedies and test them, we must have an approximately accurate knowledge of the movement of population and of the causes of death." (Chapin.)

MEDICAL NOTES.

WORK OF THE ADIRONDACK COTTAGE SANITARIUM.—In the eighteenth annual report of the Adirondack Cottage Sanitarium, Dr. Edward L. Trudeau sums up the work of the institution for the past year as follows: 271 patients have been treated. To 234 of these the institution has furnished the best possible means of restoration to health at a nominal cost, and to 37 entirely free of cost to them. Two years ago the free out-patient department of the sanitarium was established, which has been in constant operation since and has steadily extended its work. Free medical advice has been given, not only to patients waiting to enter the sanitarium, but also to unsuccessful applicants for admission who have remained in the town.

MEETING OF ASSOCIATION OF MEDICAL LIBRARIANS.—The sixth annual meeting of the Association of Medical Librarians was held Saturday, May 16, 1903. A large number of librarians and physicians representing the medical libraries throughout the country assembled in the morning at the Library of the Medical Society of the County of Kings, Brooklyn, N. Y., and, after an inspection of the building, were entertained at luncheon at the Union League Club by the local members, Dr. William Browning, Dr. J. M. Winfield and Mr. A. T. Huntington. The scientific sessions was held in the afternoon at the New York Academy of Medicine, the president, Dr. William Osler, in the chair. Papers and discussions were contributed by Mr. C. P. Fisher of Philadelphia, Dr. T. C. Lee of Minneapolis, Mrs. G. W. Myers and Dr. E. H. Brigham of Boston, Mr. J. S. Brownne and Dr. W. S. Dennet of New York, Mr. A. T. Huntington of Brooklyn, and others. The officers elected for the ensuing year are as follows: President, Dr. William Osler of Baltimore; vice-president, Dr. Abraham Jacobi of New York; secretary, Mr. Albert T. Huntington of Brooklyn; treasurer, Dr. George D. Hersey of Providence; executive committee, Mr. John S. Brownne of New York, Mr. Charles P. Fisher of Philadelphia, Dr. James M. Winfield of Brooklyn; manager of exchange, Miss Marcia C. Noyes of Baltimore. The meeting adjourned to meet June, 1904, at Atlantic City, N. J. A full report of the proceedings of the association will be published in the *Medical Library and Historical Journal* for July, 1903.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, May 27, 1903, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: Diphtheria 38, scarlatina 36, typhoid fever 26, measles 41, smallpox 0.

THE STILLMAN INFIRMARY AT CAMBRIDGE. — Mr. James Stillman, who had previously given \$150,000 for an infirmary at Cambridge for Harvard students, has added another gift of \$50,000 for a separate ward for contagious diseases in connection with the infirmary.

SEMI-CENTENARY OF THE MAINE MEDICAL ASSOCIATION. — The Maine Medical Association this year celebrates its fiftieth anniversary. A somewhat elaborate program, including various outings, has been prepared. According to the notice sent with the program, "the committee is striving to arrange for a meeting which shall be pleasantly memorable in every respect." We wish the association success in this laudable endeavor. The meetings will be held in Portland.

LITIGATION REGARDING SMALLPOX. — During the recent epidemic of smallpox protest was made against certain unvaccinated children being permitted in the schools of Hyde Park, Mass., although it is said that they brought certificates stating that they were unfit subjects for vaccination. Suit was brought against the town by the family of the children concerned. After a somewhat prolonged trial, in which elaborate arguments on both sides were made, the jury somewhat unfortunately failed to reach an agreement. It is reported that another trial is pending.

AMENDMENT OF NEW HAMPSHIRE MEDICAL REGISTRATION LAW. — By an amendment to the Medical Registration Law of New Hampshire, enacted by the Legislature at the session of 1903, hotel physicians employed by the landlord of a summer hotel in the care of his guests or employees will hereafter be obliged to secure a license to practice, which can be obtained only by examination. The next examination will be held at Concord, June 23 and 24.

THE LYNN, MASS., HOSPITAL. — According to the recently published annual report of the Lynn Hospital, it appears that the work of the institution has shown an increase in every department over that of previous years. During the year, 1,117 patients were admitted, with an average number in the hospital each day of 53. In the out-patient

department 13,432 cases were treated during the year, of which 4,651 were new; 61 confinement cases were treated in the maternity ward, an increase of 6 over the preceding year. It is a matter of gratification to the management of the hospital that an increasing number of persons of limited means are being treated at the hospital, who are able and willing to pay a certain amount for their care.

NEW YORK.

BILLS IN OPPOSITION TO MEDICAL SENTIMENT. — By his action in regard to two bills passed by the recent Legislature, Governor Odell has placed himself in opposition to the vigorously expressed sentiment of the medical profession and the more intelligent portion of the community at large. He signed the Goodsell-Bedell Hospital Camp Bill, regulating the establishment of tuberculosis hospitals in the various counties of the State by municipalities, corporations, associations or individuals. The special feature of it is that it prevents the erection of such hospitals without the consent of the board of supervisors of the county or the town board of the town in which it is desired to place the proposed hospital. It thus makes it impossible not only for any city but for "any fraternal order, charitable society, or philanthropic individual" to establish a hospital or even a camp for consumptives except under practically prohibitive conditions. It is felt that the approval by the Governor of this ill-advised bill puts to an end for the present, at least to a very large extent, the work of public-spirited citizens of New York State in combating and restricting the ravages of tuberculosis. The prohibition of sanatoria by the town and county authorities may be regarded as a certainty, because local interests will be arrayed against such institutions, through a mistaken idea of their dangers; and until this law is repealed an incalculable amount of injury will be inflicted. The other bill referred to is the Bostwick Bill, designed to suppress the vicious practice of substitution in the compounding of physicians' prescriptions, and this admirable measure the Governor vetoed.

NOTES FROM THE PHILIPPINES.

THE MATERNITY HOSPITAL CLOSED. — On account of lack of funds, heavy running expenses and the failure of the public to contribute sufficiently to its support, one of the most praiseworthy charitable institutions in Manila, the Maternity Hospital, has been forced to close its doors. A special plea for funds was made several months ago, and a committee of American, Spanish and Filipino ladies appointed to secure subscriptions, but sufficient money could

not be secured to enable the continuance of the institution. The hospital was started in the days of Spanish sovereignty, and was in a flourishing condition at the time war was declared between Spain and the United States. As it depended principally upon the voluntary contributions of the Spanish for support, it was forced to close in 1898, but was reopened about a year ago under the patronage of prominent Filipinos. Of late, the donations from the charitably disposed have been few, and the Managing Board has decided that the institution can no longer be continued. The children now in the asylum will be taken into the families of several wealthy Filipinos.

PERIODS OF QUARANTINE. — Owing to the existence of smallpox and plague in the city, the Board of Health has passed a resolution fixing the quarantine period for plague contacts or suspects at nine days, and of plague convalescents at thirty days. Plague contacts must go to the detention camp and plague cases to the plague hospital. Smallpox contacts or suspects must be vaccinated and be quarantined in the detention camp not less than fifteen days. Cholera cases are quarantined in the infectious disease hospital until the dejecta no longer show the presence of cholera bacilli.

QUARANTINE STATIONS AT PORTS OF ENTRY. — The marine hospital authorities are now making a tour of the southern islands with a view of locating sites for quarantine stations at the ports of entry as yet unprovided with such stations, and the work of construction will be begun as soon as practicable. While the health conditions of the Philippines are not too good in themselves, conditions in China and some of the East Indian ports are much worse, and cases of infectious disease are constantly gaining entrance to the southern islands. Hong Kong at present reports ninety-five cases of plague and smallpox. In Amoy, plague is not only very bad, but is rapidly on the increase, and the marine hospital surgeons are about to notify the steamship company running boats to Amoy that they must bring no more steerage passengers from that port for the present unless they are subjected to a fifteen-day quarantine prior to embarkation. All ships entering the port of Manila and lying at the docks are to be disinfected at Mariveles quarantine prior to arrival and departure, for the purpose of destroying any rats which may be on board. Larger steamers which load and unload by means of lighters in the bay are to be disinfected with sulphur at frequent intervals for the same purpose, but rat destruction will not be carried out as rigidly as in the case of boats which have direct communication with the shore.

Deaths reported, 3,463; under five years of age, 977; principal infectious diseases (smallpox, measles, scarlet fever, cerebrospinal meningitis, diphtheria and croup, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 757, acute lung diseases 649, consumption 359, scarlet fever 45, whooping cough 42, cerebrospinal meningitis 9, smallpox 5, erysipelas 8, measles 39, typhoid fever 65, puerperal fever 7, diarrheal diseases 92, diphtheria and croup 80.

From whooping cough, New York 9, Chicago 9, Philadelphia 5, Baltimore 1, Pittsburg 6, Boston 2, Lowell 1, Cambridge 2, Lynn 1, Somerville 2, Brockton, Everett, Brookline and Watertown 1 each. From erysipelas, Chicago 1, Philadelphia 3, and Baltimore, Pittsburg, Boston and Lynn 1 each. From smallpox, Chicago 1, Philadelphia 1, Pittsburg 3.

In the seventy-six great towns of England and Wales, with an estimated population of 15,075,011, for the week ending May 2 the death-rate was 17.5. Deaths reported, 5,049; acute diseases of the respiratory organs (London) 284, whooping cough 134, diphtheria 59, scarlet fever 56, measles 155, smallpox 15.

The death-rate ranged from 9.0 in King's Norton to 34.4 in Wigan; London 17.3, West Ham 13.5, Brighton 14.1, Portsmouth 12.8, Southampton 14.2, Plymouth 17.2, Bristol 16.2, Birmingham 19.3, Leicester 15.6, Nottingham 17.6, Bolton 17.1, Manchester 22.5, Salford 20.0, Bradford 17.5, Leeds 17.3, Hull 17.3, Newcastle-on-Tyne 19.5, Cardiff 12.1, Rhondda 19.2, Liverpool 21.5, Croydon 10.0.

METEOROLOGICAL RECORD.

For the week ending May 16, in Boston, according to observations furnished by Sergeant J. W. Smith of the United States Signal Corps:

THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE, 1903.

VAUGHAN, G. T., assistant surgeon-general. Detailed to represent the service at meeting of the Association of Military Surgeons at Boston, Mass., May 20-21, 1903.

PERRY, J. C., passed assistant surgeon. To report at Washington, D. C., May 17, 1903.

DECKER, C. E., assistant surgeon. Granted extension of leave of absence, on account of sickness, for fourteen days from April 24. May 15, 1903.

WILSON, R. L., assistant surgeon. Granted leave of absence for seven days from April 28, 1903, under provisions of paragraph 191 of the regulations.

MCLAUGHLIN, A. J., assistant surgeon. Granted leave of absence for two months from May 1. May 15, 1903.

WARD, W. K., assistant surgeon. Granted leave of absence for three days from May 14, 1903, under provisions of paragraph 191 of the regulations.

FORD, C. B., acting assistant surgeon. Granted leave of absence for fourteen days from June 3. May 15, 1903.

FRASER, A. C., acting assistant surgeon. Granted leave of absence for forty-five days, on account of sickness, from April 27. May 15, 1903.

MARSH, W. H., acting assistant surgeon. Granted leave of absence for seventeen days from May 8. May 15, 1903.

WETMORE, W. O., acting assistant surgeon. Granted extension of leave of absence for fourteen days from May 15. May 15, 1903.

BOARDS CONVENED.

Board convened to meet at San Francisco, Cal., for physical examination of an officer of the Revenue Cutter Service. Detail for the board: Passed Assistant Surgeon W. G. Stimpson, Chairman; Assistant Surgeon C. W. Vogel, Recorder.

Board convened to meet at Washington, D. C., May 25, 1903, for the physical examination of candidates for cadetship in the Revenue Cutter Service. Detail for the Board: Assistant Surgeon-General W. J. Pettus, Chairman; Assistant Surgeon-General H. D. Geddings, Recorder.

Board convened to meet at Washington, D. C., June 15, 1903, for examination of candidates for admission as assistant surgeon in the service. Detail for the board: Assistant Surgeon-General G. T. Vaughan, Chairman; Surgeon C. T. Peckham; Passed Assistant Surgeon H. S. Mathewson, Recorder.

CHANGES IN THE MEDICAL CORPS OF THE NAVY FOR THE WEEK ENDING MAY 23, 1903.

F. W. WEBER, surgeon. Granted sick leave for two months. L. MORRIS, passed assistant surgeon. Ordered to the "Minneapolis."

R. H. MICHELS, assistant surgeon. Ordered to the Asiatic Station via the "Solace."

E. M. BROWN, assistant surgeon. Detached from the Naval Hospital, Norfolk, Va., and ordered to the Naval Hospital, Newport, R. I.

J. H. HOLLOWAY, assistant surgeon. Ordered to the "Baltimore."

A. J. GEIGER, assistant surgeon. Appointed assistant surgeon from May 6, 1903.

SOCIETY NOTICES.

MAINE MEDICAL ASSOCIATION. — The semi-centenary of the Maine Medical Association will be held in Portland, Me., June 3, 4, 5, 1903.

THE MASSACHUSETTS MEDICAL SOCIETY. — One hundred twenty-second annual meeting will be held at 9 o'clock A.M., Wednesday, June 10, 1903, in Horticultural Hall, Massachusetts and Huntington avenues, Boston. Meetings of sections will be held in the Medical Library, 8 The Fenway, on the preceding day, Tuesday, June 9.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — There will be a special meeting of the society in Sprague Hall, Medical Library, on Monday, June 1, at 8.15 P.M.

The society will take action relative to the formation of an Academy of Medicine in accordance with the plan presented by the Special Committee of the society and the amendments to that plan as suggested by the Executive Committee of the Medical Library.

ARTHUR K. STONE, M.D.,
543 Boylston St. Secretary.

RESIGNATION.

DR. A. S. HARTWELL has resigned the superintendency of the Long Island Almshouse and Hospital to enter private practice.

APPOINTMENT.

DR. SIMON F. COX has resigned from the position of first medical officer at the Long Island Hospital, Boston Harbor, and has been appointed superintendent of the institution.

RECENT DEATHS.

JOHN VAN HARTLINGEN, M.D., for thirty years a practising physician in Brooklyn, N. Y., died on May 18, at the age of fifty-seven. He was born in Millstone, N. J., and was graduated from the College of Physicians and Surgeons, New York, in 1869.

JOHN B. BURDETT, M.D., of Jersey City, N. J., died on May 21, after a long illness. He was born in Bergen County, N. J., Sept. 21, 1833. He studied medicine with the late Dr. Lewis A. Sayre of New York, and was graduated from the College of Physicians and Surgeons in that city in 1856. He had practised in Jersey City since 1858.

GUSTAVE BOUCHER, M.D., who was well known in Italian circles in Brooklyn, died at the Columbus Hospital, Borough of Manhattan, N. Y., on May 21, at the age of sixty-seven. He was born in Naples, Italy, and was graduated from the university of that city in 1864. He had practised in Brooklyn for the last twelve years.

JAMES FORSAITH RICHARDS, M.D., M.M.S.S., died in Andover, May 13, 1903, aged seventy years.

HENRY ALLEN NOYES, M.D., M.M.S.S., died in Pittsfield, March 23, 1903, aged thirty-six years.

BOOKS AND PAMPHLETS RECEIVED.

Ambulance Work and Nursing. A Handbook of First Aid to the Injured, with a Section on Nursing, etc. Illustrated. Chicago: W. T. Keener & Co.

"Wild Oats": a Sermon in Rhyme. By Maurice C. Hime, M.A., LL.D. Philadelphia: P. Blakiston's Son & Co. 1903.

National Incorporation for the American Medical Association. Issued by the New York State Medical Association.

Tettenhamer on Eosinophiles. By Edward T. Williams, M.D., of Boston. Reprint. 1902.

The Ill Health of Herbert Spencer. By George M. Gould, M.D., of Philadelphia. Reprint. 1903.

International Clinics, a Quarterly of Illustrated Clinical Lectures and especially prepared Original Articles on Treatment, Medicine, Surgery, Neurology, Pediatrics, Obstetrics, Gynecology, Orthopedics, Pathology, Dermatology, Ophthalmology, Otology, Rhinology, Laryngology, Hygiene, and Other Topics of Interest to Students and Practitioners. By Leading Members of the Medical Profession throughout the World. Edited by A. O. J. Kelly, A.M., M.D., with the collaboration of eleven other physicians and with regular correspondents in Montreal, London, Paris, Berlin, Vienna, Leipzig, Brussels and Carlsbad. Vol. I. Series 13. 1903. Illustrated. Philadelphia: J. B. Lippincott Co.

The Practical Medicine Series of Year Books, comprising ten volumes on the Year's Progress in Medicine and Surgery. Issued monthly. Under the general editorial charge of Gustavus P. Head, M.D., Vol. V, Obstetrics. Edited by Reuben Peterson, A.B., M.D. April, 1903. Chicago: The Year Book Publishers.

Original Articles.

THE SYMPTOMATOLOGY AND DIAGNOSIS OF DISEASES OF THE PANCREAS.¹

BY REGINALD H. FITZ, M.D., BOSTON.²

THE consideration of the symptomatology and diagnosis of diseases of the pancreas may appropriately be introduced by referring to the memorable communication on this subject by Friedreich³ nearly thirty years ago. According to this authority "no single symptom which may occur in diseases of the pancreas is pathognomonic, and the concurrence of several does not always result in a positive diagnosis. . . . Fatty stools, mellituria, epigastric pains with the characteristics of celiac neuralgia, and a palpable tumor lead among the symptoms most useful in diagnosis;" and (p. 223) the presence of undigested, striated muscle fibers in the feces "is worthy of every consideration and may, perhaps, prove of diagnostic value."

For a while no material additions were made to our knowledge of the clinical pathology of the pancreas, but in 1887 the investigations of Müller,⁴ and especially those of v. Mering and Minkowski⁵ in 1889, excited a renewal of interest in the matter. Since then physiologists and pathologists, physicians and surgeons in various parts of the world have made numerous contributions to the knowledge of the functions and lesions of the pancreas, and this gland has become recognized as of the greatest importance in maintaining and promoting a healthy state of the body. Within the past five years have appeared the notable treatises of Körte, Oser, and, more recently, that of Mayo Robson and Moynihan. These are the authors now to be consulted for classified knowledge of the questions under consideration. From them is to be learned in what respects the clinical characteristics of pancreatic diseases are now more sharply defined than in the days of Friedreich and his predecessors.

It is generally agreed that the symptoms especially suggestive of pancreatic disease are dependent largely upon the resulting disturbances of its functions and upon the situation of the organ. The former include the various modifications in the composition of the urine and feces; the latter comprise the localized resistance, tenderness and pain, and the evidence of obstruction of the gastro-intestinal and biliary tracts. Unfortunately for diagnostic purposes, the functions of the pancreas are not the exclusive property of this gland, but are possessed to a greater or less extent by other structures and other agencies.

For more than a century it has been known that diabetes may be associated with disease of the pancreas. More than eighty years ago visible fecal fat was found to hold a like relation. Forty years later the presence of undigested muscle fibers in the feces first attracted attention. These observations have since been repeated with sufficient

frequency to lead the physician to suspect, often to assert, the presence of disease of the pancreas when one or more of these conditions have been determined. The comparison, however, of the results of anatomical investigation with clinical observation makes it evident that diseases of the pancreas much more frequently occur without the recognition of glycosuria and fat and muscle in the feces than when these abnormalities are apparent.

The physician, therefore, wishes to know if one or more of these conditions are present in some diseases of the pancreas, why are they not present in all? If found in a certain instance of a single variety, why are they not present in all or in most of the cases of this particular affection? Morbid changes of the pancreas are found frequently after death without symptoms having been observed during life to indicate their presence. On the other hand, the diagnosis of probable pancreatic disease, perhaps of the gravest sort, has been made from the recognition of one or more of the symptoms or signs which, at times, have been found associated with alterations of the pancreas, and the patient has recovered or the gland when exposed has presented no abnormal appearance.

From the data collected by Oser it is evident that the symptoms attributable to disturbed pancreatic function are almost invariably connected with chronic lesions productive of extensive destruction of pancreatic tissue or with interference to the passage of its secretion into the intestine. The pancreatic lesions usually associated with diabetes are those in which the common element of interstitial inflammation exists with a corresponding destruction of the parenchyma of the gland. This may occur in the form of the genuine, granular atrophy of Hansemann, in calculous pancreatitis, or in the sequence of chronic suppuration, cysts and tumors.

Visible fecal fat and azotorrhea, on the contrary, are oftener associated with chronic conditions interfering with the flow of pancreatic juice into the intestine, as obstruction of the ducts from calculi, stricture or tumors, than with those causing destruction of the secreting cells of the gland. Rarest of all is the presence of alterations which are associated with diabetes, and fat and numerous muscle fibers in the feces. The case reported by Fles⁶ is almost unique in these respects. His diabetic patient ate much bacon and fat meat, and evacuated so much unabsorbed fat that it could be scooped by the ounce from the feces. The latter contained also large numbers of undigested, striated muscle fibers. The autopsy showed that the pancreas was represented only by fragments of its fibrous framework and scarcely recognizable traces of the gland substance. The duct could not be found. Nevertheless it is evident from human pathology that extensive destruction of the pancreas may take place without observable modification of function. Franke⁷ extirpated a cancerous pancreas, and although the patient lived five months after the operation, there was glycosuria merely for a few days, and the stools appeared normal. The patient of Trafoyer⁸ was well seventeen years after a pancreatic slough was discharged from the bowel.

The inference from such observations is that in extensive destruction of the pancreas without obvious disturbance of function enough of the gland is left intact, or an accessory pancreas or other organs or agencies are present, to assume the pancreatic functions. Even when the pancreas presents an apparent integrity and fatal diabetes exists, the researches of Ssobolew⁹ and Opie¹⁰ make it evident that destruction of the islands of Langerhans may have taken place. Their investigations, and those of other observers directed to this possibility, add force to the suggestion that in the destruction of these islands may lie the important factor in explanation of diabetes in certain of the cases in which the gross appearances of the pancreas are normal. Hence with the recognition of various causes of glycosuria and diabetes, these affections, in the light of our present knowledge, are attributable to disease of the pancreas only in those instances in which there is extensive degeneration or destruction either limited to these islands or affecting also the parenchyma of the gland.

If the diabetes is associated with long-continued bronzing of the skin and enlargement of the liver, in the absence of jaundice and the characteristic distribution of the pigment in Addison's disease, the suggestion is direct that chronic fibrous pancreatitis is present. Since the original publication by Hanot and Chanfard¹¹ on this subject, the bronzed diabetes of French writers, Anschütz¹² has tabulated twenty-four cases of this combination. The view that the affection of the pancreas is the remote result of the deposition of the pigment in the hemochromatosis of v. Recklinghausen has repeatedly been favored by recent writers.¹³

Steatorrhea is next in importance to glycosuria and diabetes as evidence of disturbance of pancreatic function, although the views concerning its significance are somewhat divergent.

The presence of oil readily attracted attention, but it soon became apparent that the fat might assume a solid as well as a liquid form. It was considered that the presence of visible fat represented an increase of this constituent, the absorption of which was interfered with in consequence of the disease of the pancreas. Müller,¹⁴ however, called attention to the frequent concurrence of disturbance of biliary secretion in the cases reported. He emphasized the importance of a lack of bile in the intestine as interfering with the absorption of fat, and considered it doubtful if a lack of pancreatic juice could cause steatorrhea. He endeavored to show that a deficiency of split fat, the proportion of total fecal fat being normal, was the chief feature when there was lack of the pancreatic juice, and that interference with the flow of bile was the main cause of pathological steatorrhea. Müller reported but three cases of pancreatic disease in support of his views. Jaundice was present in one only. In another the actual condition of the pancreas and its duct was not to be determined, as the patient was seen after having been operated upon for "cyst" of the pancreas.

In order to obtain further clinical evidence on this point, a table has been prepared to show the relation between visible fecal fat, jaundice and pancreatic disease. Only those cases are included which give anatomical evidence at an autopsy, a laparotomy or by the passage of a pancreatic calculus that there was actual disease of the gland.

¹⁴ Loc. cit.

Twenty-nine cases of steatorrhea are the basis of this table. Jaundice was present in 12 and absent in 17. Among those with jaundice, tumors, chiefly cancer, were present in 8. The lesions existing in the remaining 4 cases were a cyst in 1, and induration, rarefaction and fatty transformation in 3, in which also there was either obstruction or obliteration of the duct. Of the 17 cases of steatorrhea without jaundice, in 7 the lesions were tumors, chiefly cancer; in 6 calculi were present; 2 were fatty, and 2 were single examples of cyst and atrophy.

It was considered interesting to note also the relation of diabetes or glycosuria to the steatorrhea. Diabetes was present in 11 cases and absent in 18. The lesions present in the former series were tumors, chiefly cancer in 4, calculi in 4, a cyst in 2, and fatty degeneration in 1 instance. Among the 18 cases of steatorrhea without diabetes were 11 of tumors, chiefly cancer; 2 of calculi, 2 of fatty transformation, and 1 each of atrophy and induration. Visible fecal fat, jaundice and diabetes were present in 3 cases only. 2 of tumor and 1 of cyst. This table, therefore, does not support the view that jaundice is an important factor in the origin of the fatty stools connected with disease of the pancreas. It suggests that in about three fifths of the cases of steatorrhea attributable to pancreatic disease there is neither diabetes nor jaundice, that in two fifths there is either diabetes or jaundice, in about equal proportion, and in but few instances is there a combination of diabetes and jaundice.

Müller's researches were of value in another direction, by calling attention to the clinical importance of a chemical analysis of fecal fat in cases of suspected disease of the pancreas. A table has been prepared showing the analyses given by him and others of the percentage of fat extracted from the feces in health, catarrhal jaundice and in diseases of the pancreas with and without jaundice. The last mentioned include only those actually demonstrated either by the knife or by the passage of a typical calculus.

It is evident from this table that the feces of the healthy individual contain about 20% of unabsorbed fat and that in catarrhal jaundice this ratio may be doubled. In affections of the pancreas the percentage of unabsorbed fat is generally not much increased, except when jaundice is an accompaniment, thus sustaining the position of Müller.

In health this extracted fat contains from 20% to 30% of neutral fat, and from 70% to 80% of split fats, namely, fat acids and soaps. In ten cases of disease of the pancreas the neutral fat ranged from 17.50% to 91.6%. In but two of these was the percentage of neutral fat below normal, while in nine of them it was largely or greatly increased. That of split fat, on the contrary, was decidedly diminished in nine out of eleven patients. In the remaining two it was as high as in health. The table thus bears out the view of Müller, though not without exceptions, that in pancreatic disease there is less splitting of the fat and consequently an increase of the neutral fat, thus giving a satisfactory explanation of the oily stools of the older observers.

On the other hand, there is a sufficient lack of anatomical control to permit his conclusions to be accepted without question. Enough pancreatic juice may have been supplied to affect the results of chemical analysis in many of the cases of obstruction of the duct of Wirsung by a flow through the duct of Santorini. If both ducts were closed and the pancreas extensively diseased an accessory pancreas may have existed. Müller himself recognized the influence of intestinal bacteria and gastric contents¹⁵ in splitting fat, although he regarded their importance as slight. It is obvious too, as stated by him, that the feces may contain an excess of fat not only in cases of jaundice, but also when there is a superabundance of fat in the food, and when there is disease of the absorbents within or without the intestinal wall.

Steatorrhea, therefore, is to be regarded as evidence of disease of the pancreas only when other

causes of its presence can be excluded, the most important of which is interference with the flow of bile into the intestine. Its recognition depends not merely on the presence of fat resembling oil, butter, lard or tallow, but in doubtful cases requires the skill and facilities of the chemist trained in physiological methods.

The probability that steatorrhea due to extensive disease of the pancreas may exist for years without disturbance to the general health is suggested in the communication of Walker.¹⁶ His patient, a physician, free from jaundice, passed for twenty years large colorless stools of a peculiar putrid odor, occasionally accompanied by free oil or fat, liquid or solid. During this period he was in perfect health and in the active pursuit of his profession. He died at the age of ninety years. There was no marked absence of fat. The pancreas was large, apparently composed of nearly pure fat. The duct was rendered almost absolutely impermeable within an inch of the duodenum by a very irregular calculus.

Despite the attention which has been given since the time of Friedreich to azotorrhea, as manifested by the presence of numerous undigested muscle fibers in the feces, but little clinical evidence has been offered that this sign is likely to prove of especial value in the diagnosis of diseases of the pancreas.

gestive of disease of the pancreas. These are notably excessive in quantity as compared with that of the food taken, and are composed of unabsorbed muscle fibers, fat and carbohydrates. He has met with this condition in a number of cases in which the suspicion of pancreatic disease was confirmed.

The various possible disturbances of function in pancreatic disease have generally been sought by inspection and microscopical examination, and by the use of the simplest chemical and physical methods. It must be recognized, however, that any considerable disturbance in the digestion and assimilation of fat, muscle and carbohydrates from affections of the pancreas has almost invariably been connected with extensive and protracted lesions. It is obvious, therefore, that feeding with an increased quantity of one or the other of these constituents of diet in suspected cases of pancreatic disease might be followed by appreciable changes in the secretions and excretions earlier than otherwise would have been the case. It is clear, also, that disturbances in the digestion of fats, starches and proteids, relieved by the addition of pancreas or its preparations to the diet, provided disease of the digestive glands could be eliminated, might furnish additional evidence in favor of the pancreatic source of the disturbance.

It has repeatedly been noted that the fecal fat

In the preparation of the accompanying table but 8 cases have been found which fulfil the demanded requirements. In 6 sugar was present in the urine; in 5 there was visible fecal fat, and jaundice was present in 2 instances. In Lichtheim's case the diabetic patient's diet was composed largely of meat, but diarrhea existed, a combination sufficiently explanatory of azotorrhea without the assumption of the presence of disease of the pancreas. The relative frequency of steatorrhea as compared with azotorrhea indicates that proteids are better digested than fats if the supply of pancreatic juice is notably diminished. Any increase of undigested muscle fibers in the stools would be significant of pancreatic disease only when gastric digestion was relatively normal, and there was neither excess of meat in the diet nor diarrhea.

Bulky stools are mentioned by Oser¹⁷ as sug-

has been observed when the patient was eating abundantly of fat. It is desirable, therefore, in possible cases of pancreatic disease to increase the quantity of fat in the diet nearly to the limit which is to be reached without producing steatorrhea in healthy persons or in patients not suffering from disease interfering with the absorption of fat. It is particularly desirable to determine the toleration of fat in those cases of diabetes in which the pancreas presents no abnormal conditions. These limits are not sufficiently known at present, chiefly because the thorough appreciation of this method of investigation demands the use of especial training and a properly equipped laboratory.

Hartsen¹⁸ gave eight to ten teaspoonfuls of cod liver oil to two diabetic patients, in each of whom extreme atrophy of the pancreas was found, but there was no unusual quantity of fat observed in the feces.

¹⁶ Med. Chir. Trans., 1889, lxxii, 257.

¹⁷ Deutsche Klinik., 1901, v, 165.

¹⁸ Nothnagel's Sp. Path. u. Ther., 1898, xvii, 21.

Müller,¹⁹ despite an almost exclusive milk diet in his case of cyst of the pancreas, found only a trifling increase in the fat extracted from the feces and but little variation in the split and neutral fats from that observed when a mixed diet was taken. Herter gave an exclusive milk diet to Northrup's patient with probable cancer of the pancreas. Although the feces had been regarded as fatty before this test was applied, no chemical analysis of their composition was reported. While the milk diet was being taken (see table) there was a large excess of fat in the feces, although there was no considerable modification in the percentage of neutral fats. The especial change seems to have been an increase in the percentage of fat acids and a diminution in that of the soaps. The reported cases are few in which pancreatic disease has been found after death, and properly controlled dietetic tests with fat have been made during life. Important additions to our knowledge are likely to be made by further observations in this direction.

In like manner should be tested the capacity of the patient for digesting muscle in the intestine as compared with that of the normal individual or with one suffering from affections in which there is no reason for supposing that the pancreas or intestine is diseased. For this purpose it is important first to determine the condition of the gastric functions and then to introduce into the intestine the muscle fiber, as free as possible from the influence of gastric digestion. It may be that the glutoid capsules of Sahli, to be mentioned later, will suffice for the latter purpose, or that other more satisfactory means may be devised. Müller found well preserved muscle fibers in his case of cyst of the pancreas when the patient was not eating more meat than a healthy adult could easily digest. A similar appearance was observed during several days while the patient was taking but little meat. The evidence furnished by this patient has only a relative value, since the nature of the lesion was determined by a surgical operation and the condition of the pancreatic duct was known.

The possibility of testing the efficiency of the pancreas by attempting to produce an alimentary glycosuria also demands consideration. The researches of Wille²⁰ in this direction are especially significant. This observer gave at breakfast to each of eight hundred patients 100 gr. of glucose in a half liter of tea or coffee. This quantity was selected with the view that the limit of physiological glycosuria lay between doses of 150 and 250 grammes. The urine of the patients was collected every two hours after the glucose was taken. In fifteen of seventy-seven patients who died, glycosuria occurred, and the postmortem examination showed alterations of the pancreas. In certain instances the changes were slight and ascertained only by microscopical examination. The test was positive in three out of four cases of cancer of the pancreas. Unfortunately, the ease with which a similar result is obtained with this test in a great variety of conditions in which there is no reason to suspect disease of the pancreas makes it of little value in diagnosis under present conditions.²¹ The

comparison of the quantities of glucose necessary and the percentages of sugar obtained may lead to additional information.

The functions of the pancreas may be tested also by the use of agents which demand largely the action of the pancreatic juice to promote their absorption and elimination. Salol was first suggested for this purpose by Ewald and Sievers.²² It had been stated by Nencki that salol was split by pancreatic juice into salicylic acid and phenol, and that the former could readily be detected in the urine. It was recommended that the salol be given in capsule or in pills coated with keratin. A delay in the cleavage would suggest retention in the stomach or deficiency of pancreatic juice. Sahli²³ has suggested the use of "glutoid" capsules containing iodoform, to determine the presence of pancreatic secretion in the intestine. It is claimed that these capsules are sufficiently hardened in formaldehyde to withstand powerful gastric digestion for at least twelve hours, although rapidly digested in pancreatic juice. If there is normal motility of the stomach the iodine reaction will appear in the saliva in from four to six hours after the capsule containing the iodoform is swallowed, provided there is a satisfactory pancreatic digestion and there is no interference with intestinal absorption. Sahli²⁴ reports a number of cases in which the reaction was delayed for twenty-four hours or more, and obstruction of the pancreatic duct from cancer of the gland was found.

The late reaction is evidence of defective pancreatic digestion only when there are normal gastric motility and intestinal absorption. If the latter is defective and there is diarrhea the undigested capsule may be found in the feces. Fromme²⁵ applied this test in a case proving to be one of inoperable sarcoma of the omentum. Visible fecal fat was present, but neither jaundice nor glycosuria. The reaction did not appear till the end of twenty-seven hours. In a patient who was found to have a "cyst" of the pancreas the glutoid capsule test gave only a slightly delayed reaction, from seven and a half to nine hours. Although these cases were reported to illustrate the inaccuracy of the test the evidence given is insufficient to exclude closure of the pancreatic duct in the first, and it is possible that the "cyst" of the pancreas was an omental bursitis or, if of the pancreas, that there was no considerable interference with the passage of the pancreatic juice into the intestine.

The suggestion is obvious that if symptoms attributable to disturbed functions of the pancreas be present and other conditions, especially jaundice, be absent, the use of pancreatic preparations or of minced pancreas might favorably affect these disturbances and thus indirectly confirm the diagnosis of pancreatic disease. Fles²⁶ gave daily a calf's pancreas to his patient with atrophied pancreas and unrecognizable duct. The fat and muscle fibers disappeared from the feces, to return again when the pancreas was omitted from the diet. Repeated instances of the disappearance of visible fat from the feces and of improvement in diabetics have followed the use of pancreas and its preparations, but

they are not included in this consideration as lacking the control of anatomical investigation.

The examination of the urine for pentose has attracted attention since the statement by Hammarsten²⁷ that the pancreas contained a nucleo-proteid, the cleavage of which produced pentose. Salkowski, who had discovered the condition pentosuria, recognized the identity of the pentosazon in the pancreas and that in the urine and suggested that pentosuria might be regarded as an affection of the pancreas. Blumenthal²⁸ showed that the condition might be persistent during a period of five months. Pentose was usually sought with phenylhydrazin, acetic acid and heat. Mayo Robson²⁹ states that Cammidge obtained yellow crystals in sheaves and rosettes from the urine of a patient with chronic pancreatitis by boiling it for a short time with an oxidizing agent and adding phenylhydrazin. Urine from a case of catarrhal jaundice gave a negative result when similarly treated. It was suggested by him that this test might prove useful in diagnosis. Further evidence is needed before any diagnostic importance in connection with pancreatic disease is to be attached to the presence of these crystals, since an osazon of similar appearance has been obtained by the action of phenylhydrazin on normal urine. Blumenthal,³⁰ moreover, was able to isolate nucleo-proteids from various organs and find pentose in them, which obviously excludes the pancreas as the necessary place of their origin.

It is known that the putrefaction of the proteid contents of the intestine is caused by bacteria and that their action is enhanced by the presence of pancreatic juice. In consequence the aromatic compounds, indol, skatol and phenol, are formed, and the quantities of indican and of ethereal sulphates in the urine give evidence of the extent of the proteid putrefaction and indirectly of the condition of the pancreas. Gerhardt³¹ observed an absence of indican in the urine in a case of obstruction of the small intestine, in which condition, according to Jaffé, it should have been increased. After the patient's death acute hemorrhagic pancreatitis and an obstructed pancreatic duct were found. Gerhardt suggested that the absence of indican when the small intestine was obstructed might be regarded as evidence of disease of the pancreas. Two confirmatory and one contradictory observations have been made. Oser, however, maintains that variations in the excretion of indican may have no direct relation to disease of the pancreas, hence be of no diagnostic value.

The quantity of ethereal sulphates eliminated seem to have a more constant relation to the extent of intestinal putrefaction and to the secretion of pancreatic juice. The clinical observations on these points, especially those sufficiently controlled, are few. Herter found increased indican and an increased ratio of ethereal to pre-formed sulphates in Northrup's case, in which disease of the pancreas, though not the condition of the duct, was ascertained. Edsall³² concludes, in his communication on this

subject, "if, with suspicion of pancreatic disease, factors which usually cause an increase of the ethereal sulphates be present and yet the values be found low, the test would at present appear to be of distinct practical importance in diagnosis. Constipation, gastric hypoaecidity or anacidity, icterus, grave anemia, and cachexia are very likely to cause an increase in the relative or absolute values of the ethereal sulphates."

Finally, Opie³³ has suggested the possibility of discovering in the urine the fat-splitting ferment set free in acute pancreatitis. He endeavored to determine its presence in one case by following the method proposed by Cassell and Loevenhardt, which is based upon the decomposition of ethyl butyrate by the ferment and the production of butyric acid. The urine neutralized with potassium hydroxide was divided into two portions, one of which was boiled for the purpose of destroying the ferment. Ethyl butyrate was added to each specimen. That unboiled after twenty-four hours gave an acid reaction, while the boiled specimen showed little if any change.

The symptoms which have proven most useful in diagnosis are those which call attention directly to the region of the pancreas. They are the epigastric pain, tenderness, tension and tumor, with or without obstructive jaundice, and evidence of mechanical interference with the motility of the stomach and duodenum.

Pain, when present, usually is manifested early in the course of the disease and may be the initial symptom. It often suggests gastric cramp or intestinal or biliary colic. It is occasional, paroxysmal or persistent, dull or sharp, squeezing, tearing or piercing, mild or severe, even agonizing, and not infrequently is associated with signs of collapse. It may be clearly defined near the median line, midway between the ensiform cartilage and the navel, or may shoot laterally, especially towards the left side. It occasionally is continued upwards into the thorax or downwards into the lower abdomen.

Tenderness is a frequent accompaniment, especially of persistent pain. It often is described as sensitiveness, and although usually limited to the epigastrium, may be found in the region of the spleen or in the left groin. Ultimately tender spots may appear in remoter parts of the abdomen, especially when disseminated foci of fat necrosis accompany the pancreatic affection.

Epigastric tension often is observed and may be apparent at the outset or develop later in the course of the disease. When an early symptom it is followed soon by a circumscribed, tympanitic, epigastric swelling, evidently due to gaseous distention of the stomach. The resistance found late in the course of pancreatic disease is due to the formation of a tumor. When the latter is the result of disease of the pancreas its characteristics depend largely upon the nature of the affection. Small, circumscribed, dense tumors result from chronic inflammation or neoplasms, usually of the head of the gland, while large, tense tumors of pancreatic origin in the left half of the epigastrium or symmetrically involving more or less of the upper abdomen are indicative generally of cysts of the pancreas or of collections

of fluid in the omental bursa, more common than the former and generally confounded with them.

Jaundice, commonly slight and of short duration, is occasionally encountered in acute affections of the pancreas. Then it is oftener seen in the course of a few days after the onset of the attack than as an earlier symptom. Prolonged jaundice is a frequent accompaniment of chronic affections of the head of the pancreas, especially of fibrous inflammation and neoplasms. The association of the jaundice with distention of the gall bladder is sufficiently frequent, as noted by Courvoisier and others, to make this combination suggestive rather of disease of the pancreas than of affections of the biliary tract.

Motor disturbances of the stomach and intestine are among the usual symptoms associated with pancreatic disease. Vomiting, sometimes frequent or incessant and often distressing, is customary among the early symptoms of acute pancreatitis, and constipation, at times obstinate, is the rule. So constant are these motor disturbances that the frequent diagnosis in cases of acute pancreatitis is acute intestinal obstruction.

The prolonged motor insufficiency of the stomach mechanically induced by chronic affections of the pancreas, especially from enlargement of the head of the gland, not infrequently give rise to dilatation of the stomach. In consequence frequent or persistent vomiting may take place late in the course of pancreatic disease.

Although the diagnosis of diseases of the pancreas in the light of our present knowledge practically depends more on the symptoms calling attention to the locality of the organ than upon the evidence of disturbances of its function, it is reached eventually by the exclusion of other sources of the local symptoms than the pancreas.

The differential diagnosis lies first between acute and chronic affections and second between the several varieties of chronic pancreatic disease. The former include pancreatic hemorrhage and the hemorrhagic gangrenous and suppurative varieties of acute pancreatitis, all of which are characterized by similar symptoms and some of which presumably represent stages of the same affection. The latter include chronic pancreatitis with or without calculi, cysts and tumors.

Of acute pancreatitis it may be said now as in 1889³⁴: "The symptoms are essentially those of a peritonitis beginning in the epigastrium and occurring suddenly, during ordinary health, without obvious cause. The diagnosis, therefore, is based on pain, tenderness and tympany limited to the region of the pancreas, and on the gradual development of a deep-seated peritonitis in the same place.

DIFFERENTIAL DIAGNOSIS.

The differential diagnosis lies practically between an irritant poison, perforation of the digestive or biliary tracts and acute intestinal obstruction. An irritant poison is excluded by the history of the case and by the examination of the vomit. Perforating ulcer of the stomach or duodenum is to be excluded by the absence of pain after eating, hemorrhages from the digestive canal and cachexia.

Acute perforation of the transverse colon is rare, and the resulting peritonitis progresses more rapidly and is likely to be general. Perforation from gall-stones is usually preceded by attacks of biliary colic and jaundice, while the seat of the pain is rather in the region of the gall bladder than in that of the pancreas. Acute intestinal obstruction is most likely to give rise to doubt. It is to be eliminated by determining the potency and capacity of the large intestine, by the rarity in the epigastrium of an obstructed small intestine, by the immediate presence of localized tenderness and by the usual absence of conspicuous, general tympany or limited distention of intestinal coils."

In the cases of acute pancreatitis thus far reported no new evidence, unless that of Opie be confirmed, has been furnished which gives to the diagnosis more than a variable degree of probability. Certainty has been reached only by a laparotomy or a postmortem examination. The former has made clear the condition of the pancreas by the usual disclosure of multiple areas of disseminated fat necrosis, a condition occurring on an extensive scale only in the sequence of acute pancreatitis, or by the demonstration of the enlarged, hemorrhagic or necrotic pancreas as the focus of the surrounding peritonitic manifestations. Fortunately the exploratory laparotomy in an increasing number of cases has proven the most satisfactory method of treatment, and, like most abdominal operations for the relief of acute symptoms, is the more helpful the earlier in the course of the disease it is performed.

The diagnosis of chronic pancreatic affections is based usually on the occurrence of localized pain and upon the presence of a tumor. The pain may exist without the tumor, but the latter is rarely present without the former at some time during its formation. The pain of chronic pancreatic affections is often a deep-seated discomfort; when severe it is likely to be paroxysmal and then is suggestive of biliary colic, but is referred rather to the region of the pancreas than to that of the biliary tract. The tumor is of slow or rapid growth, large or small, perhaps distinctly palpable only in narcosis, fixed or slightly movable, and with or without symptoms of pressure upon the surrounding parts. Its position behind the stomach and above or behind the colon is made apparent by inflation and percussion of these portions of the alimentary canal. Evidences of disturbance of pancreatic function are to be sought along the lines previously mentioned, but experience has shown that definite and convenient additions to our knowledge must be made before functional disturbances of the pancreas can be ascertained sufficiently early and with sufficient certainty to render assured the pancreatic source of the disease. The discovery of sugar in the urine should lead to the examination of the feces for fat. The presence of the latter should suggest the search for undigested muscle fibers and for glycosuria, and alimentary and therapeutic tests should be applied to all suspected cases.

The differential diagnosis lies between chronic pancreatitis, with or without pancreatic calculi, cysts and tumors.

The association of jaundice with tumor has led to the diagnosis of chronic pancreatitis and to its effective treatment by Mayo Robson and others.

³⁴ Fitz, *Acute Pancreatitis*. The Middleton-Goldsmith Lecture for 1889.

The relatively rapid formation of the tumor in the sequence of symptoms suggestive of gall-stones may serve in certain instances to differentiate this condition from malignant neoplasms. The discovery of characteristic calculi in the feces has made clear in a few instances the source of discomforting or severe symptoms without tumor in the region of the pancreas, and exploratory laparotomies have confirmed or suggested the diagnosis of neoplasms of this organ.

The various possibilities of a more accurate study of the symptomatology and diagnosis of diseases of the pancreas suggest an early advance in our knowledge of the subject. With the increase of clinical laboratories in our general hospitals and with the more frequent addition of biological chemists to the force of pathologists, the errors of the past are likely to be avoided and new lines of research are sure to be planned.

SMALL CONTRIBUTIONS TO THE SURGERY OF THE INTESTINAL TRACT.¹

BY JOH. VON MIKULICZ, M.D., LL.D., BRESLAU, GERMANY.

WHEN your President requested me to address your society on the subject of abdominal surgery I had originally intended to give the address a larger scope, as befitting your society. Unfortunately, I was unable to write up such a subject, owing to numerous demands made upon my time. Suffice it, therefore, to speak on some minor topics of intestinal surgery, and to apologize to you for the trivial character of the communications. Moreover, I cannot refer to the literature on the matter, nor — as I ought to — mention the authorities who have treated these lesions successfully.

(1) ON CARDIOSPASM AND ITS TREATMENT.

The first subject on which I shall speak is the so-called "cardiospasm." You are all well acquainted with a certain affection of the esophagus which consists mainly of a sacculated, or fusiform, dilatation of the organ, most pronounced in the lowest portion of the esophagus. Zenker, who first has accurately described such cases, considered the lesion an idiopathic dilatation of the esophagus. This disease occurs mainly during middle life, but has also been found in old age. It is characterized by a difficulty in swallowing either liquid or solid food, until in the advanced stage of the affection only very small amounts of food can reach the stomach. The cause of this difficulty lies in the fact that the esophagus retains a portion of the ingesta instead of being completely emptied during each act of swallowing, as is normal. In advanced stages this residue amounts to a quarter or even half a liter, and the patient finally dies of inanition.

Since I first began to examine the esophagus with the esophagoscope, I have observed about

twenty cases of this affection — during the last seven years alone I have taken careful notes on fourteen cases. Twenty years ago, when I made the first esophagoscopical examinations, I showed that in all these cases there exists an abnormal occlusion of the cardiac orifice of the stomach which I consider due to a muscular spasm. I have therefore designated and described this affection under the name of "cardiospasm." While under normal conditions during the act of swallowing the cardiac orifice opens automatically, and easily admits the food into the stomach, it remains closed in case of cardiospasm, and this spasm must be overcome by the contraction of the muscular wall of the esophagus. This leads to an excentric hypertrophy of the esophageal wall, and the organ becomes more and more dilated as the free passage of the food is interfered with. Another consequence of this impeded passage of the food is a chronic esophagitis, caused by the decomposition of the contents.

This affection can be definitely diagnosed in the living subject only by means of the esophagoscope: without the esophagoscopical examination the nature of the disease can only be surmised; in many cases carcinoma of the cardiac orifice of the stomach will be suspected. Also Röntgen-rays can be of great value for the diagnosis of this affection. I should like to show you some photographs to prove this (demonstration). The affection which I have described is a primary cardiospasm, if no other lesions are demonstrable. There is, however, a secondary cardiospasm which I have occasionally observed in cases of carcinoma of the cardiac end of the stomach. This secondary cardiospasm is originally entirely different from the secondary dilatation of the esophagus, in consequence of actual esophageal carcinoma.

Two of the fourteen cases of primary cardiospasm were peculiar, in that they were followed by secondary carcinomata. In each case the carcinomatous growth was found in the first thoracic portion of the esophagus, above the dilatation. One case was diagnosed by esophagoscopical examination, the second at the autopsy. I wish to show you an illustration of the esophagus in the latter case.

I refrain from discussing the etiology and the pathogenesis of the cardiospasm, because we are only able to surmise at present. I am convinced that we have to deal with an abnormal muscular contraction of the cardiac orifice. In regard to therapy we were until recently able to do very little; regular washings of the esophagus, and removal of the decomposing residue, can relieve only the secondary esophagitis. In severe cases the patients must be fed with the tube; with very little practice the patient learns to pass the tube into the stomach. If this method is unsuccessful, we must resort to a gastric fistula.

I have repeatedly attempted to dilate the contracted cardiac orifice, partly by passing fairly thick bougies, partly by inserting into the cardia a permanent canula supplied with a valve which allows liquids to pass into the stomach but prevents a backward flow.

Neither of these methods has proved particularly successful. I decided, therefore, to resort to heroic measures in the case of a female patient of twenty-

¹ Read before the American Surgical Association, Washington, D. C., May 13, 1903.

three years who was suffering intensely from the affection. The stomach was exposed by laparotomy, and an incision was made into the anterior wall wide enough to allow the entire left hand to pass into the stomach. Under the guidance of my fingers, which I pushed forward toward the cardiac end, I introduced an instrument resembling a glove-stretcher into the cardiac orifice; the dilatation was gradually affected to such an extent that the blades of the instrument were about 7 cm. apart. Thus I caused a blunt dilatation of the cardia similar to the dilatation of the sphincter ani in case of anal fissure. Then I closed the wounds in the stomach and in the parietal walls. It was a complete success; a fortnight after the operation the patient partook of solid food. During a period of observation extending over three months the patient was able to swallow every kind of food without any difficulty. She claimed never to have been in as good physical

between the stomach and the jejunum, that is, at the artificial anastomosis, or it may be situated some centimeters—sometimes 10 cm.—away from the anastomosis. Since the wall of the jejunum is considerably thinner and less resistant than that of the stomach, serious complications are more apt to follow after jejunal ulcer than after gastric ulcer. These complications are: Perforation into the abdominal cavity and death from subsequent peritonitis, or more frequently a gradual perforation through the anterior abdominal wall, usually at the site of the left rectus abdominalis, that is, a penetrating ulcer with inflammatory infiltration of the anterior abdominal wall; we have then the well-known pseudo-tumor, which sometimes occurs with gastric ulcer, and which results from this inflammatory infiltration of the abdominal parietes. If the affection is recognized early, excision of the gut and suture may effect a cure; and this has been done in

CASES OF THE I DO NOT KNOW WHETHER MORE CASES OF
this disease have been observed in America, and I
should be very much interested to hear what were
the experiences of my American colleagues in the
matter. In our experience, peptic ulcer of the
jejunum occurs only after gastro-enterostomy per-
formed for benign affections of the stomach, such
as gastric ulcer or pyloric stenosis. Moreover, it
appears only after anterior gastro-enterostomy
according to Woelfer's method—but it does not
after v. Hacker's posterior gastro-enterostomy. It
develops either during the first weeks after the
operation, or it may delay for several months.
The general picture of the disease closely resembles
that of gastric ulcer; hence most cases were
formerly regarded as a recurrence of the original
trouble. Pain is a prominent symptom; it is very
severe, and is increased by the ingestion of food.
The ulcer lies either at the point of junction

been normally diluted and neutralized by bile and
by the pancreatic secretion. On a recent visit to
the Johns Hopkins Hospital in Baltimore, I had
an opportunity of seeing a preparation which
showed the formation of peptic ulcers in the
jejunum of a dog after gastro-enterostomy. This
occurred during the course of some experiments
made by Dr. Stephen Watts, second assistant sur-
geon at that institution. An anterior or rather a ven-
tral gastro-enterostomy was performed by suture
without mechanical appliances. The dog died after
three months. At the autopsy two ulcers were
found in the jejunum opposite to the opening in
the stomach. One of these had perforated, and
caused the death of the animal.

This shows the possibility of the formation of
such ulcers in animals as well as in man.

All these observations—I believe—are very
important in deciding upon the best and safest

The relatively rapid formation of the tumor in the sequence of symptoms suggestive of gall-stones may serve in certain instances to differentiate this condition from malignant neoplasms. The discovery of characteristic calculi in the feces has made clear in a few instances the source of discomforting or severe symptoms without tumor in the region of the pancreas, and exploratory laparotomies have confirmed or suggested the diagnosis of neoplasms of this organ.

The various possibilities of a more accurate study of the symptomatology and diagnosis of diseases of the pancreas suggest an early advance in our knowledge of the subject. With the increase of clinical laboratories in our general hospitals and with the more frequent addition of biological chemists to the force of pathologists, the errors of the past are likely to be avoided and new lines of research are sure to be planned.

lowest portion of the esophagus. Zenker, who first
has accurately described such cases, considered the
lesion an idiopathic dilatation of the esophagus.
This disease occurs mainly during middle life, but
has also been found in old age. It is character-
ized by a difficulty in swallowing either liquid or
solid food, until in the advanced stage of the affec-
tion only very small amounts of food can reach
the stomach. The cause of this difficulty lies in
the fact that the esophagus retains a portion of the
ingesta instead of being completely emptied dur-
ing each act of swallowing, as is normal. In
advanced stages this residue amounts to a quarter
or even half a liter, and the patient finally dies of
inanition.

Since I first began to examine the esophagus
with the esophagoscope, I have observed about

we have to deal with an abnormal muscular contrac-
tion of the cardiac orifice. In regard to therapy we
were until recently able to do very little; regular
washings of the esophagus, and removal of the
decomposing residue, can relieve only the secondary
esophagitis. In severe cases the patients must be
fed with the tube; with very little practice the
patient learns to pass the tube into the stomach. If
this method is unsuccessful, we must resort to a
gastric fistula.

I have repeatedly attempted to dilate the con-
tracted cardiac orifice, partly by passing fairly thick
bougies, partly by inserting into the cardia a per-
manent canula supplied with a valve which allows
liquids to pass into the stomach but prevents a
backward flow.

Neither of these methods has proved particularly
successful. I decided, therefore, to resort to heroic
measures in the case of a female patient of twenty-

¹ Read before the American Surgical Association, Washington, D. C., May 13, 1903.

three years who was suffering intensely from the affection. The stomach was exposed by laparotomy, and an incision was made into the anterior wall wide enough to allow the entire left hand to pass into the stomach. Under the guidance of my fingers, which I pushed forward toward the cardiac end, I introduced an instrument resembling a glove stretcher into the cardiac orifice; the dilatation was gradually affected to such an extent that the blades of the instrument were about 7 cm. apart. Thus I caused a blunt dilatation of the cardia similar to the dilatation of the sphincter ani in case of anal fissure. Then I closed the wounds in the stomach and in the parietal walls. It was a complete success; a fortnight after the operation the patient partook of solid food. During a period of observation extending over three months the patient was able to swallow every kind of food without any difficulty. She claimed never to have been in as good physical condition; her weight increased, and her general appearance was much improved; and the esophagoscopic examination has shown that the cardiac orifice is no longer tightly contracted, but opens normally during retching and swallowing.

The period of observation in this case is too short to draw a definite conclusion about the value of the operation which I have described to you—I performed the operation about four months ago. Considering the insufficiency of all therapeutic measures for this affection, I do not hesitate, even now, to advise the performance of this operation. Personally I should not again make as large an incision into the wall of the stomach, but should prefer to introduce the dilator through a small gastric fistula; or one might construct an instrument which could be introduced into the cardia through the mouth, and act as a dilator.

(2) ON PEPTIC ULCER OF THE JEJUNUM.

The second subject of which I shall briefly speak is the so-called peptic ulcer of the jejunum, an affection which, as you know, has only recently been observed by surgeons, and only as a sequel to gastro-enterostomy. As far as I can gather from the accounts published by our German colleagues, about fifteen cases of this disease have been met with by Steinthal, Kocher, Heidenhain, Goepel, Kroenlein, Hahn and myself—I have seen five cases of it. I do not know whether more cases of this disease have been observed in America, and I should be very much interested to hear what were the experiences of my American colleagues in the matter. In our experience, peptic ulcer of the jejunum occurs only after gastro-enterostomy performed for benign affections of the stomach, such as gastric ulcer or pyloric stenosis. Moreover, it appears only after anterior gastro-enterostomy according to Woelfer's method—but it does not after v. Hacker's posterior gastro-enterostomy. It develops either during the first weeks after the operation, or it may delay for several months. The general picture of the disease closely resembles that of gastric ulcer; hence most cases were formerly regarded as a recurrence of the original trouble. Pain is a prominent symptom; it is very severe, and is increased by the ingestion of food. The ulcer lies either at the point of junction

between the stomach and the jejunum, that is, at the artificial anastomosis, or it may be situated some centimeters—sometimes 10 cm.—away from the anastomosis. Since the wall of the jejunum is considerably thinner and less resistant than that of the stomach, serious complications are more apt to follow after jejunal ulcer than after gastric ulcer. These complications are: Perforation into the abdominal cavity and death from subsequent peritonitis, or more frequently a gradual perforation through the anterior abdominal wall, usually at the site of the left rectus abdominalis, that is, a penetrating ulcer with inflammatory infiltration of the anterior abdominal wall; we have then the well-known pseudo-tumor, which sometimes occurs with gastric ulcer, and which results from this inflammatory infiltration of the abdominal parietes. If the affection is recognized early, excision of the gut and suture may effect a cure; and this has been done in a few cases. However, there is a strong tendency to recurrence; in one of my own cases resection of the gut was followed by a new ulcer 10 cm. from the site of the first.

In most of these cases of jejunal ulcer there has been a marked hyperacidity of the gastric juice, but there are exceptions; thus Kocher found in one case a diminished amount of hydrochloric acid and even a trace of lactic acid in the gastric juice. In this direction I have made an especially interesting observation in the case of an infant of three months: The patient suffered from congenital stenosis of the pylorus, accompanied by an immense hypertrophy of the pyloric muscle, as is usual in such cases. Two months after the operation there appeared multiple jejunal ulcers, which caused the death of the child through profuse intestinal hemorrhage and peritonitis. I show you here a picture of this last case. Since the stomach during infancy contains only a small amount of hydrochloric acid, and an examination of the contents of the stomach has proved this in my case, hyperacidity of the gastric juice could not be the cause of jejunal ulcer in this patient.

Nevertheless, we are pretty certain about the etiology of peptic ulcer of the jejunum; it can be explained only by the prolonged presence of gastric juice, which reaches the jejunum without having been normally diluted and neutralized by bile and by the pancreatic secretion. On a recent visit to the Johns Hopkins Hospital in Baltimore, I had an opportunity of seeing a preparation which showed the formation of peptic ulcers in the jejunum of a dog after gastro-enterostomy. This occurred during the course of some experiments made by Dr. Stephen Watts, second assistant surgeon at that institution. An anterior or rather a ventral gastro-enterostomy was performed by suture without mechanical appliances. The dog died after three months. At the autopsy two ulcers were found in the jejunum opposite to the opening in the stomach. One of these had perforated, and caused the death of the animal.

This shows the possibility of the formation of such ulcers in animals as well as in man.

All these observations—I believe—are very important in deciding upon the best and safest

method of operating for gastric ulcer or pyloric stenosis. After these observations we are not entitled, in my opinion, to perform anterior gastro-enterostomy any longer—at least, not for benign affections of the stomach. For carcinomatous stenosis of the pylorus it may be considered, being technically the more simple operation. For the benign affections of the stomach we must choose an operation which does not expose the jejunum to the immediate action of the gastric juice, that is, an operation which restores as far as possible normal physiological conditions. The most rational method is the pyloroplasty operation, especially with Finney's modification. If this is not feasible we have to choose between gastro-duodenostomy—which recently has been advocated by Kocher—and v. Hacker's posterior gastro-enterostomy.

(3) ON OPERATIVE TREATMENT OF SEVERE FORMS OF INVAGINATION OF THE INTESTINE.

My third subject concerns the treatment of the severe forms of invagination of the intestine when disinvagination is impossible. In such cases resection of the invaginated portion of the gut offers the only possibility of saving the patient. However, this method, as usually practiced, is extremely dangerous, so that even the operation rarely restores the patient. Especially great is the danger of peritonitis. I have treated two cases in the following manner, which, in my opinion, offers the best chances for the patient's life; and indeed both cases made an uncomplicated recovery. The first case was that of a woman of twenty-seven years, the wife of a Polish merchant, who was admitted to the surgical clinic of Breslau in March, 1902, presenting the symptoms of intussusception. The patient had been sick for five weeks, presenting the characteristic symptoms of invagination, which had increased in severity up to the day of admission. Besides general meteorism, vomiting, and all other signs of intestinal obstruction, there had frequently been bloody stools. Inspection and palpation of the abdomen revealed a painful cylindrical tumor, about as thick as a man's arm, which began at about the middle of the transverse colon and ran toward the left side, corresponding in general to the direction of the descending colon, and went down into the pelvis. Examination of the anal region revealed a dark reddish-brown tumor of about the size of a fist, covered with intestinal mucosa, and protruding from the widely dilated anal orifice. Digital examination showed that this tumor was nothing but the lower end of the intussusceptum, extending into the rectum, and therefore connected with the tumor palpated through the abdominal wall. Further examination showed the prolapsed portion of intestine to be the cecum with the ileo-cecal valve, the lowest portion of which was already partly gangrenous. Thus we had here a case of ileocolic intussusception, the oral end of the large intestine being invaginated into the aboral portion down to the rectum, having dragged with it a portion of the ileum as an intussusceptum.

In view of the prolonged existence and the great extent of the invagination, as well as of the fact

that part of the intussusceptum had become gangrenous, there could be no thought of reduction by manipulation. Resection alone could be considered. However, the ordinary operation of resection seemed too heroic a measure, considering the poor state of the patient (pulse 140). She seemed unable to withstand the risk of a peritoneal affection which is incurred with the ordinary method of intestinal resection. I therefore proceeded in the following manner, which almost completely excluded the danger of a post-operative peritonitis:

An incision 20 cm. long was made along the border of the left rectus abdominis. When the abdominal cavity was opened a small amount of a brownish-red, turbid exudation was found and evacuated; the descending colon, much stretched, congested, and presenting an edematous infiltration, appeared in the opening. It was distended and showed numerous irregular transverse folds resulting from an axial dragging of the mesentery which was invaginated along with the gut. The colon was drawn up into the wound, so as to expose freely a strip of its anterior wall, about 5 to 6 cm. wide. In this position it was stitched to the abdominal wall by a series of sutures through the serous covering, and thus the parietal layer of the peritoneum was united to the visceral layer; this completely excluded the exposed portion of the colon from the peritoneal cavity. In a few places where the sutures did not seem to be quite efficient to connect the two layers owing to the transverse folds of the colon wall, small tampons of iodoform gauze were used to fill any remaining gaps.

The anterior wall of the colon, thus excluded from the peritoneal cavity, was opened by a longitudinal incision about 12 cm. in length. This incision exposed the intussusceptum, which at this point had not undergone any severe disturbances of circulation, but showed in many places ulcerations due to the pressure of the intussusciptens. The intussusceptum thus exposed consisted of two tubes of intestine, one contained within the other, the outer being colon, the inner ileum. These tubes of intestine were in contact with each other on their serous surfaces.

Hence, if the invaginated gut was to be resected at this point, it became necessary to open also the peritoneal sac, which had been dragged into the intussusceptum. In order to avoid all danger of infection in this direction I resected the invaginated gut in exact accordance with the method which I had advised for the resection of simple prolapse of the rectum, that is, the outer and inner layers of the intussusceptum were cut away step by step, and a deep catgut suture was immediately put in to close the peritoneal pocket as soon as it was opened. The site of the operation was, meanwhile, continually flushed with a normal salt solution. Thus the gut was cut and sutured at once along its entire circumference, until the mesenteric attachment was reached. In separating the mesentery we resorted to multiple ligation. Here a small strip of iodoform gauze was inserted in order to drain the mesenteric pocket into the gut. After complete resection we had to extract the resected portion which extended to the rectum. Attempts

to do this from the rectum were unsuccessful, because the intussusceptum was too tightly held by the rectum and the sigmoid flexure. By slow and careful traction we succeeded in removing it through the abdominal wound. The intussusceptum was about 45 cm. long; it consisted of a double tube, the outer being colon, the inner ileum. So the length of the entire excised portion of intestine was about a meter.

The further procedure, as well as the course of the disease, presented nothing remarkable. The main cause for congratulation was the total absence of any peritonitis, so that recovery was uninterrupted. A large artificial anus had been made by the operation, through which all fecal matter was discharged. This artificial anus was closed about eight weeks later. The patient left the clinic cured.

The same method was used with equal success in the case of a second woman of thirty-five years.

(4) ON OPERATION ON MALIGNANT GROWTHS OF THE LARGE INTESTINE.

In regard to the fourth topic I shall be brief, since I can refer to the paper which I read before the Congress of German Surgeons at Berlin a year ago. It deals with the operation for the removal of malignant tumors of the large intestine. Statistics collected until now show that the prevalent method of excision of the tumor and immediate suture of the intestine gives very bad results; the mortality varying between 30 and 50%; and most patients succumbing to peritonitis. The cause of this phenomenon is found, I believe, mainly in the secondary changes which take place in the intestinal walls under the influence of carcinomatous stenosis. The gut is dilated, its nutrition impaired and its muscular wall is insufficient; consequently after the operation we are apt to have complete atony of the intestine,—the contents are arrested at the site of the suture, the suture yields, and peritonitis results. For this reason Bloch as early as 1892 advocated operating in selected cases in two sittings. Allingham and W. Edmunds also have divided the operation in special cases. For a number of years I have, invariably, performed the operation in two sittings, and have found that the results were infinitely better than formerly. Of twenty-four cases operated on, only four died after the operation; but in none of these cases can the method of procedure be held responsible for the fatal termination. One patient died eleven days after the operation of embolism of the lung; another after a week of pneumonia; a third six weeks after the operation of general carcinomatosis, and the fourth within two days of peritonitis, caused by rupture of the carcinomatous gut during the enucleation of the tumor, so that a large amount of infective intestinal contents reached the peritoneal cavity during the operation.

As regards the technique of the two operations performed by myself, I should like to say the following. The primary incision, the enucleation of the tumor, the removal of the lymphatic glands, in short, the entire operation is performed exactly as

when one operation only is done. If now the tumor has been freed and completely enucleated, it is drawn out of the wound, the loop of gut is stitched to the parietal peritoneum with sutures including only the serous coat, and the abdominal wound is closed, leaving only room enough for the loop of the gut. Now only after the abdominal cavity is completely closed, the tumor is excised, and an artificial anus is established which is closed in two to four weeks, according to the usual methods. The disadvantage of this process is that the patient is afflicted for a few weeks with an artificial anus; but I believe that this is fully balanced by the advantage of greater safety.

In closing, I should like to say that in my experience the permanent results after operation for malignant tumor of the large intestine are very favorable, at least more so than is generally supposed. I think we should strongly point out this fact to the physicians who are still very sceptical about this operation. In compiling the joint statistics of my clinic and that of Koerte, I find that among twenty-four cases which were under observation more than four years we have nine cases without any recurrence. Among these nine are several that have been under observation much more than four years. I operated on my first case seventeen years ago, while I still conducted the clinic at Krakow.

THE SURGERY OF THE SIMPLE DISEASES OF THE STOMACH.¹

BY B. G. A. MOYNHAN, F.R.C.S., LEEDS, ENGLAND.

MR. PRESIDENT AND FELLOWS: May I be permitted at the outset of my paper to express my most cordial thanks to the fellows of the American Surgical Association for the signal honor which has been conferred upon me in asking me to present a paper to this meeting? There are few incidents so grateful to a surgeon, there can be none more encouraging, than a recognition from those best qualified to judge of the work which he is striving to do. My earnest hope is that my contribution to your proceedings may in some small measure repay you for the great courtesy which you have shown to me today:

I propose to deal in my paper with the surgery of the simple, that is, the non-malignant, diseases of the stomach. The subject, I am well aware, is one that has been debated at previous meetings of this association, but you will, I think, agree that there is still much that has to be learnt, there is still much that may engage us in profitable discussion, and I do not think, therefore, that any apology is needed for this choice of a subject.

The great majority of the simple diseases of the stomach which can be successfully treated by surgical measures are due to ulceration or to its complications and results. These various conditions can be dealt with in the following order: (1) perforation of gastric or duodenal ulcers; (2) hemorrhage from gastric or duodenal ulcers; (3) chronic ulcer, its various clinical types; (4) hour-glass stomach.

¹ Read before the American Surgical Association, May 13, 1903.

PERFORATION OF GASTRIC OR DUODENAL ULCERS.

The perforation of gastric or duodenal ulcer is one of the most serious and most overwhelming catastrophes that can befall a human being. The onset of the symptoms is sudden, the course rapid, and unless surgical measures are adopted early, the disease hastens to a fatal ending in almost every instance.

Perforation of the stomach is usually described as being of two varieties, *acute* and *chronic*; but there is an intermediate class of case, not embraced by either of these terms, which is best described as *subacute*.

In *acute perforation* the ulcer gives way suddenly and completely. A larger or smaller hole results, and through this the stomach contents are free to escape at once into the general cavity of the peritoneum.

In *subacute perforation* the ulcer probably gives way almost as quickly as in the acute form, but owing to the small size of the ulcer, or to the emptiness of the stomach, or to the instant plugging of the opening by an omental flap or tag, or to the speedy formation of lymph which forms, as it were, a cork or lid for the ulcer, the escape of fluid from the stomach is small in quantity and the damage inflicted thereby is less considerable. The symptoms at their onset may be as grave as those in acute perforation, but on opening the abdomen the ulcer may be seen to be sealed over, and no further escape of fluid is occurring.

In the subacute form of perforation I have found that there is always a complaint of greater discomfort for several days preceding the rupture. Vague general or localized pains have been felt in the abdomen, or a sharp spasm or "stitch" when the patient turned quickly, or attempted to laugh. One girl, a housemaid, felt the pain down her left side especially when reaching up to her work; another said it hurt her to bend, as her side felt stiff. These premonitory symptoms are important, and if recognized they should enable us to take measures to prevent the occurrence of perforation. They doubtless have their origin in a localized peritonitis, and the stiffness is due to the unconscious protection of an inflamed area by a muscular splint.

In *chronic perforation* the ulcer has slowly eaten its way through the stomach coats, and a protective peritonitis has had time to develop at the base. The escape of stomach contents is therefore local merely; barriers of lymph confine the fluid to a restricted area and perigastric abscess forms. A chronic perforation occurs more frequently on the posterior surface of the stomach, and the perigastric abscess occasioned thereby is recognized as "subphrenic." The acute and subacute forms of perforating ulcer are more common on the anterior surface.

There can be no doubt that recovery by medical treatment alone is possible both in the acute and in the subacute forms of perforation. I have had two cases under my care in which a diagnosis of perforation had been made by competent medical men. In both an operation was impossible, as no skilled help was available until the urgency of the symptoms seemed to have passed off. When I operated, many months later, the evidence of peri-

tonitis completely surrounding the stomach was undeniable. Though patients may recover, their recovery cannot be urged as a reason for the delay or withholding of surgical help in all cases. For the possibility of spontaneous recovery, though not denied, is yet so remote as to make it imperative to adopt operative treatment at the earliest possible moment. The risk of operation is definite, the hazard of delay is immeasurable. There are times when the diagnosis may be difficult. If morphine has been administered to still the intolerable pain, the patient's condition becomes placid and comfortable. It may be almost impossible then to recognize the extreme urgency of the case. In such circumstances I have, however, placed great reliance upon a continued hardness and rigidity of the abdominal muscles. Even when the patient expresses herself as free from pain, when the aspect has become natural, and when the pulse has returned to the normal, the abdominal rigidity remains. In the case of I. S., a girl aged seventeen, upon whom I operated for a perforated duodenal ulcer, the medical man who sent her to the infirmary had diagnosed a perforated gastric ulcer, and had told the patient and her parents that immediate operation alone could save her life. Having obtained consent to operation, he despatched the girl to the infirmary and gave a hypodermic injection of $\frac{1}{4}$ gr. morphine to lessen the distress of the journey. When I saw her shortly after her arrival, she looked in perfect health, she had no suffering, and her pulse and respirations were normal. The abdomen, though not distended, was absolutely rigid and immobile, and I did not hesitate to operate at once. In any uncertain case I should incline to operation rather than to indefinite postponement to solve the diagnosis.

I have seen a difficulty in diagnosis arise, and I know of three cases in which negative exploration has been performed, when the patient was a woman at the commencement of a menstrual period. From some unexplained and indeterminate cause a sharp attack of abdominal pain, followed by vomiting, distention, prostration and collapse had occurred in all, and had caused a confusion in the diagnosis. In the case under my own observation a history of previous similar, though less severe, attacks at the menstrual epoch, and the absence of any marked abdominal stiffness or tenderness, though the belly was obviously distended, enabled me to negative the question of perforating ulcer of the stomach.

The operation should be conducted speedily, and all means adopted to save the patient from shock. The excision of the ulcer is not necessary. My practice is to close the ulcer at once by a single catgut suture taken through from side to side, so as to prevent any further leakage during the application of the sutures. I apply two continuous sutures of Pagenstecher thread, which infold the ulcer and a portion of healthy stomach around it. After the stitches are completed, the cleansing of the peritoneum is begun. If there is much soiling a free flushing of the cavity is necessary; if the operation is done within ten to twelve hours a gentle wiping of the surrounding area with wet swabs will suffice. Drainage, as a rule, is not necessary, except in the very late cases, but when adopted it should be free and, if necessary, a second suprapubic incision

should be made. I have preferred the enlarging of the original incision and free flushing through that, to the method of multiple incisions advocated by Finney. One point I think requires emphasis: it is the multiplicity of perforating ulcers. As soon as the ulcer first discovered is sutured a rapid survey of the whole stomach is desirable, in order that any other ulcer may be laid bare. An examination of a large number of recorded cases has shown that double perforation occurs in no less than 20%. In the majority the second ulcer was on the posterior surface at a point exactly apposed to the first. In duodenal ulceration the perforation may be very large; the ulcer seems to have fallen out bodily. When the gap is stitched up a narrowing of the caliber of the duodenum results, and it may therefore be necessary to give an alternative route from the stomach by performing gastroenterostomy.

(2) HEMORRHAGE.

The bleeding from gastric or duodenal ulcers is recognizable either as hematemesis or melena. In lesser degree these symptoms are seen not infrequently; in their severer forms they are of dire significance, and may be the sole cause of the patient's death. It is but rarely that the surgeon is called upon for so momentous a judgment as is necessary in cases of severe hematemesis or severe melena. For the condition of the patient is poor, even at times desperate. Operative intervention is therefore hazardous; yet a continued bleeding will, in certain cases, inevitably end in death.

It is necessary at the outset to emphasize the fact, a fact frequently ignored, that hemorrhage may manifest itself under entirely different circumstances in different patients. In some it is the earliest and for a time the only symptom of gastric disturbance; in others it is the last expression in a long and tedious course of symptoms. In other words, the hemorrhage may occur from an *acute* or from a *chronic* ulcer of the stomach or duodenum. It will be found when the clinical history of a series of cases is examined, that whereas in the latter the bleeding varies within the widest limits both as regards quantity and frequency, in the former the clinical history is repeated in case after case in a most remarkable manner.

Hemorrhage from an acute ulcer.—Under the term "*acute ulcer*" of the stomach are probably included several varieties of pathological conditions, which are different in causation, different in destiny, but alike in the single fact that their clinical recognition is due to the bleeding which occurs from them, in abundant quantity. There is the ordinary peptic ulcer, there is the minute erosion barely recognizable even on close scrutiny, which yet opens up a vessel, and there are "weeping patches" and "villous areas" and similar indeterminate and unnumbered conditions which have been recognized when the stomach has been explored during life. To the clinician all these conditions are betrayed by their tendency to hemorrhage.

In almost every instance the hemorrhage is the first symptom. Even on close enquiry it is difficult to elicit any history of antecedent gastric discomforts. The vomiting of blood comes unex-

pectedly and suddenly, a large quantity of blood is lost and the patient suffers, often in an extreme degree, from the symptoms of hemorrhage. The pulse becomes feeble and fluttering, the face waxen, the breathing rapid and shallow, the body surface cold or clammy. For a time the symptoms may give rise to serious alarm, but a rally is seldom long delayed. The bleeding is checked spontaneously, and vomiting is rarely repeated, or if repeated the quantity of blood lost is but small.

In several of my cases a sudden, apparently causeless hemorrhage, has ushered in a long train of symptoms of dyspepsia. The acute ulcer has been the precursor, or rather the earliest stage, of a chronic ulcer.

The characteristics of hemorrhage from an acute gastric ulcer are, therefore: *Spontaneity, abruptness of onset, the rapid loss of a large quantity of blood, the marked tendency to spontaneous cessation, the infrequency of a repetition of the hemorrhage in anything but trivial quantity, and the transience of the resulting anemia.*

Hemorrhage from a chronic ulcer.—The bleeding from a chronic ulcer of the stomach or duodenum may vary within the widest limits both of frequency and of quantity. For convenience of description I should arrange the cases in four groups:

(1) In the first the hemorrhages are latent or concealed. The blood is small in quantity, and may be recognized only after minute examination of the stomach contents or of the feces. The estimates given by various writers, as to the occurrence of hemorrhage in ulcer, vary between 20% and 80%, and we are entitled to assume that this wide divergence of statement is due not so much to differences in the symptoms of ulcer but rather to the varying degrees of closeness with which the cases are observed, and to differences in the frequency and minuteness of examinations of the stomach contents or the feces. It would probably not be rash to assume that all ulcers of the stomach or duodenum bleed at some time or other, but if the bleeding be trivial and infrequently repeated, it is never likely to obtain clinical recognition.

(2) In the second group those cases should be included which are characterized by intermittent hemorrhage. The bleeding is copious, but transient, and occurs at intervals of two, three or more months. An exemplary instance of this class is the following:

A. S., female; aged twenty-eight. In May, 1898, the patient had a sudden attack of profuse bleeding from the stomach. She was in bed six weeks. For eighteen months after this her health was very poor, indigestion was constant, vomiting was occasional, constipation was invariable. For six months she was then in fairly good health, and was able to take food much better. In April, 1900, indigestion became severe, and a copious hemorrhage again occurred. Treatment was continued for six months with much benefit. In January, 1902, a third attack of hematemesis and fainting; after this she was kept in bed for four weeks. In September, 1902, again hematemesis as severe as before. From then to January, 1903, she was under constant treatment, but improvement was very slow. Anemia has been a prominent symptom since April, 1900. At the

operation a large ulcer was found in the stomach, and a second in the duodenum. Gastro-enterostomy was successfully performed.

In all the cases in this group indigestion is a prominent symptom. The hemorrhage often occurs without cause, but at times there may have been noticed an exacerbation of gastric discomfort and uneasiness for a few days. Anemia is almost constant.

(3) In the third group the cases are characterized by hemorrhages, which are rapidly repeated, and on all occasions abundant. In the majority of patients the symptoms of indigestion which have been noticed for months or years before have undergone an appreciable increase in the recent days. Then, suddenly, the hemorrhage occurs, a large quantity, a pint or a pint and a half, of blood is vomited. The patient may faint from loss of blood; he shows, always, the general symptoms of bleeding. For twelve or twenty-four hours the vomiting ceases, to reappear at the end of this time, without apparent cause, and in equal or greater quantity. A second latent period is followed by a further hemorrhage, and so the patient becomes in a condition of the gravest peril.

No better example of this class could be cited than the following: M. W., female; aged twenty-four. Has suffered from symptoms of gastric ulcer, pain, vomiting and inability to take solid food for fifteen months. Eleven weeks before admission to hospital all her symptoms became worse. Vomiting became frequent; pain was almost intolerable. During the five weeks before admission she vomited daily, and on almost all occasions some blood came. While waiting in the hospital she vomited three times in five days, and on each occasion about half a pint of blood came. She was very blanched. Pulse 112. The motions were tarry on two occasions. At the operation two old scars and one showing recent inflammation were seen. Gastro-enterostomy led to perfect recovery.

(4) The fourth group would comprise those cases in which the hemorrhage occurs in enormous quantity, inundating the patient and leading to almost instant death. The opening of the splenic artery, the aorta, the vena cava, or the pancreaticoduodenal vessels, allows of the so rapid escape of blood that the patient dies as surely and as swiftly as if his carotid or femoral vessels were divided. Such cases fortunately are rare. In my own experience only one such example has occurred, a large oval opening being then found in the splenic artery.

If, then, we accept the classification of cases of hemorrhage from gastric or duodenal ulcer into the four groups suggested, we may define their characteristics as follows:

(1) The hemorrhage is latent or concealed, is always trivial and often conspicuous.

(2) The hemorrhage is intermittent, but in moderate quantity, occurring spontaneously and with apparent caprice at infrequent intervals. The life of the patient is never in jeopardy from loss of blood, though anemia is a persisting symptom.

(3) The hemorrhage occurs generally but not always after a warning exacerbation of chronic symptoms. It is rapidly repeated, is always abundant, its persistence and excess cause grave peril, and will, if unchecked, be the determining cause of the patient's death.

(4) The hemorrhage is instant, overwhelming and lethal.

THE TREATMENT OF HEMORRHAGE.

(A) *From an acute ulcer.*—If what has been said of the characteristics of hemorrhage from an acute ulcer prove to be true, it is clear that the aid of the surgeon will rarely need to be invoked. Medical means alone will suffice in almost every instance to ensure the recovery of the patient. Though the hemorrhage is alarming from its suddenness and intensity, it may confidently be predicted that, in the majority of cases, it will not recur; or that if it recur, the quantity lost will almost certainly be small.

There are, however, a few cases in which the hemorrhage may be both copious and recurring, and may threaten the life of the patient. Under such circumstances an operation may be required. An examination of the recorded cases has convinced me that wherever surgical treatment is deemed advisable gastro-enterostomy, speedily performed, will prove the surest means of leading to the arrest of the bleeding. In not a few records one reads that the whole surface of the mucosa seemed to be "weeping blood," that multiple points of oozing appeared scattered irregularly over the stomach wall, or that a definite source of the blood, any point from which the blood chiefly ran, could not be ascertained. The surgeon has then fallen back upon styptics or the cautery, or the ligaturing of a villous patch in mass. It is difficult to convince one's self that any of these procedures have had the smallest effect for good; and in some the bleeding has recurred after the operation, and has determined the fatal issue. A search for a bleeding point is futile, harmful and, in my judgment, quite unnecessary. The performance of gastro-enterostomy will prove more effective than any other procedure, both in checking the hemorrhage and in preventing its recurrence.

(B) *From a chronic ulcer.*—It is mainly in regard to the cases included in Group 3 of the classification given above that the question of surgical treatment will arise. If we picture to ourselves the pathological conditions present in such a case, it will be seen that, though the bleeding may be spontaneously checked for a time, it will show a marked tendency to recur. The base of the ulcer is, as a rule, densely hard, and the vessel traverses it like a rigid pipe. The vessel is eaten into, as it were, by the ulcer, which erodes one side, leaving a ragged hole. Owing to the stiffening by chronic inflammatory deposit, the artery is unable to contract or retract, and the bleeding can, therefore, only be checked by the plugging of the opening by a thrombus. That such a plugging does occur there can be no doubt, for in one case I have seen it during life; on gently detaching the clot the bleeding began at once with furious onset. The tendency, indeed, even in a chronic ulcer such as I have depicted, must be to spontaneous cessation, for in no other way can the stopping and recurrence of bleeding, constantly seen, be explained. There is some condition as yet uncertain which is responsible for the detaching of the plug. This condition, I venture to think, is distention of the stomach, whereby the base of the ulcer is stretched and the

clot disturbed; for my record of cases shows indisputably that a gastro-enterostomy performed upon a patient suffering from this form of bleeding suffices to check the tendency to further hemorrhage, and permits of the speedy healing of the ulcer. In all patients so suffering a prolonged search for the ulcer in the stomach is injudicious, and the ulcer when found may, as the result of firm fusion with an adjacent structure, be irremovable. In two cases I have excised the ulcer; in the first the ulcer was on the posterior surface of the stomach, and to the opening left by its removal I anastomosed a loop of the jejunum; in the second the ulcer lay on the anterior surface near the lesser curvature towards the cardia. In this I did not perform gastro-enterostomy. In all the other cases that I have operated upon I have not attempted to deal directly with the ulcer, but have hastened to perform gastro-enterostomy. Of all the patients the one upon whom I did not perform a gastro-enterostomy was the only one I lost; the others recovered speedily and without further sign of hemorrhage.

In some cases an examination of the stomach may reveal two chronic ulcers or more, from each one of which the blood may be coming. To deal with each would be inadvisable or impossible. Cases, moreover, are recorded in which after an ulcer had been excised or ligatured in mass the bleeding had recurred and proved fatal.

In all cases, therefore, of hemorrhage from a chronic ulcer, an operation ought to be performed at the earliest possible moment. Search for, and local treatment of, the ulcer or ulcers are not necessary. A gastro-enterostomy will, without doubt, prevent a recurrence of hemorrhage and lead to a rapid healing of the ulcer from which the blood has come.

The suggestion of Dr. W. L. Rodman that the ulcer-bearing area of the stomach should be removed by partial gastrectomy is one that merits, and will doubtless receive, the careful and favorable consideration of surgeons.

CHRONIC ULCER.

Chronic ulcer of the stomach may present itself clinically in a great diversity of form. In some the onset is brusque, a copious hemorrhage from an acute ulcer being the first manifestation of gastric disease; after the lapse of a few days or weeks, however, gastralgia, vomiting and other symptoms appear, and the chronic ulcer is established. In others the onset is latent, and the early symptoms subdued. A patient may say that for several months a trivial, vague uneasiness has been experienced, that would have been forgotten but for the later accession of severer symptoms. In still others the course of the disease may present very remarkable intermissions. For several weeks the symptoms may be most marked and disabling, hemorrhage may occur on one or more occasions, but gradually an improvement is observed, and, after a time, all the distress may rapidly subside, leaving the patient in good health. The appetite may be restored, and the body weight may increase by a stone or even more. After a few months' interval a recurrence of the symptoms is observed, all the details of the former illness are repeated and

fresh hemorrhage may occur. And so the history may be repeated. In these circumstances the symptoms are due perhaps to the breaking down in the scar of a solitary ulcer, or to the fresh outbreak of ulcerated patches in other parts of the organ; of the two possibilities the former is probably the more frequent.

I have no doubt that many patients who have died from supposed malignant disease of the stomach have suffered from nothing but chronic ulceration. The induration which a persisting ulceration may cause is remarkable both for its extent and for its extraordinary mimicry of the appearances of malignant disease. In some of my own cases, and especially in one case of hour-glass stomach, the mass of inflammatory tissue was, with the knowledge I then possessed, absolutely indistinguishable by inspection and palpation from a malignant growth. Recently, however, I have in doubtful cases been able, I think, to distinguish chronic inflammatory masses by their perfect smoothness of surface. A malignant growth is always irregular, knotted, nodular or "gritty" on the surface; an inflammatory mass is more smoothly rounded off, and there is often a milky opacity of the peritoneum. The frequency with which carcinoma will develop in chronic ulcer is now generally acknowledged. Hauser estimates the frequency at 6%, a proportion which seems to me to be in excess of the truth. In my own experience only one case has been recognized.

The pathological conditions caused by chronic ulceration in the stomach are of great variety. When marked cicatricial contraction occurs the viscus is narrowed at the site of the ulcer, and an hour-glass stomach, or a trifid stomach, or a dilated stomach due to pyloric or duodenal stenosis results. If the ulcer slowly deepen a perigastritis is produced, and the stomach may become anchored to the abdominal wall, or the pancreas, or the liver, or any other neighboring structure. In all these conditions, and in others where no warping of the stomach can be found, an inveterate dyspepsia is a common symptom.

It has been the immemorial custom to look upon dyspepsia as due, chiefly, if not solely, to deficiency in the quantity or quality of the gastric juice, to some lack of adequate power in the stomach as a secreting organ. But dyspepsia of the intractable, constantly recurring form is more often a matter of physics than of chemistry. In several cases, as my records will show, I have operated for no other symptom than intolerable dyspepsia, when no diagnosis of pyloric obstruction, hour-glass stomach, or other mechanical deviation from the normal could be made. Yet at the operation abundant proof has been obtained that there was obvious distortion, or puckering or adhesion at one part or another of the organ; and that the stomach was crippled in the freedom of its action by these after-effects of ulceration. One observation I have repeatedly made in operating upon cases of chronic gastric and duodenal ulcers is that such ulcers are often multiple. If a well-marked ulcer is found at, say, the pyloric end of the stomach on the anterior surface, a second ulcer may be found, perhaps at an exactly apposing point in the posterior surface, perhaps elsewhere in

the stomach. Chronic gastric ulcers are in my experience rarely solitary.

The indications for operation in chronic ulcer of the stomach are of widely different character. When the ulcer is near the pylorus a dilated stomach will probably be the chief clinical sign; when the ulcer is in the body an hour-glass stomach may be caused; when the ulcer is nearer the cardiac end gastralgia and dyspepsia may be the only indications.

The evidences of old ulceration in the stomach are at times difficult to discover. A thin fibrous adhesion, a little crumpling of the surface, or a whitish blot on the serous coat may be all that is left of a patch of ulceration. When the stomach is pinched up between the fingers a little local thickening may be felt, or the mucous membrane may not, as it should, roll away from the muscular coat on gentle pressure. If in performing gastro-enterostomy the needle has to be passed through the stomach wall at the margin of an old ulcer, the different and greatly increased resistance to its passage is ample evidence of the change that has taken place. Inveterate dyspepsia is, in itself, an ample warrant for surgical treatment. Cases are within the experience of all in which prolonged medical treatment, most thoroughly and carefully supervised, proves ineffective, or if temporarily beneficial, is powerless to ward off the recurrence of dyspepsia. In such cases, be the physical signs what they may, an operation is desirable, and in my experience abundant justification for it will almost always be found when the stomach comes to be examined.

There are few beings so abjectly miserable as those who are the victims of intractable dyspepsia. The meal time which should be a delight is a time of despair and foreboding. The keen relish of good food, which the man in physical health should appreciate, is a joy unknown or long forgotten to the dyspeptic. A patient who has misery written in every wrinkle of a thin and haggard face, who by reason of long suffering and bitter experience has felt compelled to abandon first one dish and then another, till fluids alone can be taken, and these not always with impunity, a patient, to say the truth, whose whole life becomes embittered by the pangs of a suffering which he must inflict upon himself, this patient will find if a gastro-enterostomy be done for the chronic ulcer, which is the source of all his trouble, that his return to health and appetite is at first almost beyond belief.

Not a few of the patients upon whom I have operated have almost declined at the first to take the solid food, vegetables, puddings, pastry, and so forth that I have ordered them. And when the meal has been taken haltingly, and with grave doubt, a genuine surprise is expressed that no disablement has followed. Indeed, I do not know any operation in surgery which gives better results, which gives more complete satisfaction both to the patient and to his surgeon than gastro-enterostomy for chronic ulcer of the stomach.

OPERATIVE TREATMENT.

In operating upon chronic ulcer of the stomach I always perform gastro-enterostomy. It matters not

where the ulcer is placed, a gastro-enterostomy will relieve the symptoms completely and permanently, and will permit of the sound healing of the ulcer. This fact, I submit, is placed beyond dispute by the series of cases I am able to record.

At first sight it might appear desirable on all occasions or at all times when possible to excise the ulcer. Such a course is entirely unnecessary; moreover it is futile. For I have already pointed out that gastric ulcer is rarely solitary. If, therefore, two ulcers are found, or more than two, it is not always possible to say, even by close examination, which of the two is chiefly at fault. To excise all the ulcers, for I have seen a stomach so scarred that the ulcers seemed universal, is quite out of the question unless a partial gastrectomy is performed. But if the chief offending ulcer be excised, gastro-enterostomy would still, in my judgment, be necessary, for among the cases of excision of ulcer which are recorded there is not infrequent mention of little or no permanent improvement. In all cases, therefore, I submit gastro-enterostomy, and gastro-enterostomy alone, should be performed. Excision is unnecessary, often impossible, always insufficient, and is therefore not to be commended.

On three occasions I have performed pyloroplasty. The operation is one which, both from its ingenuity and its immediate success, appeals strongly to the surgeon. It is, however, unreliable, a return of the symptoms being not seldom observed. Of my three patients one remains perfectly well; the second is better but is certainly not in such good health as the average case of gastro-enterostomy; the third showed a speedy return of all the symptoms, and I then performed gastro-enterostomy with a perfectly satisfactory result. In this last case, and in others which I have seen, the return of the symptoms seemed to be due in part to a narrowing at the site of the pyloroplasty and in part to the formation of widespread and tough adhesions around the pyloric portion of the stomach, adhesion which must have seriously hampered the stomach in its freedom of action. Pyloroplasty is, in my judgment, an uncertain operation, and its results cannot compare with those seen after the operation of gastro-enterostomy.

In the performance of gastro-enterostomy I have made the anastomosis on the anterior and on the posterior surface, and I have used the Murphy button and Laplace's forceps as aids to the operation. I wish to speak gratefully of the help I have received from these instruments, but the greatest service they have rendered me is to convince me that they are entirely unnecessary. No better anastomosis is possible than that made with the simple suture, none is so safe, none so adaptable, and so far as speed is concerned I am content to abide the decision of the timekeeper. With the simple suture a gastro-enterostomy rarely takes, from the beginning of the incision to the last stitch, more than thirty minutes, and I have once completed the operation in seventeen minutes. I mention these times because I think the question of pace important. Speed is essential, haste is often disastrous; the two should be distinguished. Speed should be the achievement, not the aim, of an operator. His work must be thoroughly done, but being so done, then the quicker it is done the bet-

ter. I maintain that no time is saved by any mechanical appliance, and the operation is, with their aid, less perfect than it should be. I know the view which is held as to the worth of the Murphy button in America, and I have nothing but praise for the great ingenuity displayed in its making. But not the most ardent partisan will say that the Murphy button *never* courts disaster. I have seen two patients operated upon for intestinal obstruction caused by a Murphy button used for gastro-enterostomy—in one case the button had remained for six years. I have, myself, lost one patient from perforation of a button used in the performance of ileo-sigmoidostomy, three weeks after the operation. Now by the method of suture which I adopt for all forms of intestinal and gastric anastomoses there is no possibility—I speak positively—of present failure or of future mechanical disaster. The suture line has not leaked in one of my cases; the anastomosis is perfection. In one case of ileo-sigmoidostomy performed in acute obstruction due to cancer in the splenic flexure, the patient died at the end of twenty-three and a half hours. The anastomotic line was closed with the most minute perfection. I claim for the method that it is simple, speedy, applicable to all forms of anastomosis (and therefore time-saving in each, for the operator is quicker in a method he knows well) and is not open to the objection that future troubles are at least possible.

The following are the steps of the operation of gastro-enterostomy: The abdomen is opened to the right of the middle line and the fibers of the rectus are split. On opening the peritoneum a complete examination of the whole stomach and duodenum is made. The importance of this cannot be over-emphasized. A constriction in the body or towards the cardiac end may be most readily overlooked when, as is not uncommonly the case, a marked constriction at the pylorus, seen at once, is ample to account for all the symptoms. Cases of hour-glass stomach which have been overlooked at the operation, and a futile anastomosis made between the pyloric pouch and the jejunum, are recorded by several distinguished operators, and the mistake is an easy one to make unless one is determined to examine the whole of the stomach in every case. The importance of this examination of the whole stomach has recently received additional emphasis from the observation of a case upon which I operated a few months ago. I had diagnosed hour-glass stomach, and on opening the abdomen a perfect bilocular stomach at once was exposed. After demonstrating this I remarked that I always liked to see quite up to the cardiac before beginning my operation, and proceeding in the examination there was revealed another constriction and another loculus. There were, in fact, two constrictions and three loculi in the stomach—a trifid stomach. As soon as the operator is satisfied as to the conditions which exist, the great omentum and transverse colon are lifted out of the abdomen and turned upwards over the epigastrium. The under surface of the transverse mesocolon is exposed, and the vascular arch formed mainly by the middle colic artery is seen. A bloodless spot is chosen, a small incision made in the mesocolon, and the finger passed into the lesser sac. The

opening in the mesocolon is then gradually enlarged by stretching and tearing until all the fingers can be passed through it. It is very rarely necessary to ligature any vessel. The hand of an assistant now makes the posterior surface of the stomach present at this opening, and the surgeon grasps the stomach and pulls it well through. A fold of the stomach, about three inches in length, is now seized with a Doyen's clamp. The clamp is applied in such a way that the portion of the stomach embraced by it extends from the greater curvature obliquely upwards to the lesser curvature and towards the cardiac. The duodeno-jejunal angle is now sought and readily found by sweeping the finger along the under surface of the root of the transverse mesocolon to the left of the spine. The jejunum is then brought to the surface and a portion of it, about nine inches from the angle, is clamped in a second pair of Doyen's forceps. The two clamps now lie side by side on the abdominal wall, and the portions of stomach and jejunum to be anastomosed are well outside the abdomen embraced by the clamps. The whole operation area is now covered with gauze wrung out of hot sterile salt solution, the clamps alone remaining visible. A continuous suture is then introduced, uniting the serous and subserous coats of the stomach and jejunum. The stitch is commenced at the left end of the portions of gut enclosed in the clamp, and ends at the right. The length of the sutured line should be at least two inches. In front of this line an incision is now made into the stomach and jejunum, the serous and muscular layers of each being carefully divided until the mucous membrane is reached. As the cut is made the serous coat retracts and the mucous layer pouts into the incision. An ellipse of the mucous membrane is now excised from both stomach and jejunum, the portion removed being about one and three quarter inches in length and half an inch in breadth at the center. The stomach mucosa shows a tendency to retract; it is therefore seized with a pair of miniature vulsella on each side. No vessels are ligatured. The inner suture is now introduced. It embraces all the coats of the stomach and jejunum, and the individual stitches are placed close together and drawn fairly tight so as to constrict all vessels in the cut edges. The suture begins at the same point as the outer one, and is continued without interruption all round the incision to the starting point, where the ends are tied and cut short. It will be found that there is no need to interrupt the stitch at any point, for there is no tendency on the part of the sutured edges to pucker when the stitch is drawn tight. The clamps are now removed from both the stomach and the jejunum in order to see if any bleeding point is made manifest. Very rarely, about once in ten cases, a separate stitch at a bleeding point is necessary. The outer suture is now reassumed and continued round to its starting-point, being taken through the serous coat about one sixth of an inch in front of the inner suture. This outer stitch is also continuous throughout; when completed the ends are tied and cut short as with the inner stitch. There are thus two suture-lines surrounding the anastomotic opening: an inner, hemostatic, which includes all the layers of the gut; and an outer, approximating, which takes

up only the serous and subserous coats. For both stitches I use thin Pagenstecher thread. No sutures are passed through the mesocolon and stomach. The gut is lightly wiped over with a swab wet in sterile salt solution, the viscera returned within the abdomen, and the parietal wound sutured layer by layer. When the patient is replaced in bed the head and shoulders are supported by three or four pillows. The operation lasts from beginning to end about thirty to thirty-five minutes, but can be shortened by five or ten minutes if the condition of the patient demands it.

With regard to the after treatment there is but little to say. Nutrient enemata are given every four hours, and the bowel is washed out every morning with a pint of hot water; no fluid is given by the mouth for twelve hours, or until the ether sickness is over; then water in teaspoonful doses every fifteen minutes is given, and the quantity increased and the intervals lessened if sickness is not aroused. At the end of forty-eight hours milk and a little pudding, soups and such like are given. By the eighth day fish and minced chicken are taken, and in less than a fortnight solid food will be relished. The patient generally requires a caution not to overeat during the first month or two, for often the appetite is ravenous.

(4) HOUR-GLASS STOMACH.

By hour-glass stomach ("bilocular stomach"—"hour-glass contraction of the stomach") is understood that condition in which the stomach is divided into two compartments by the narrowing of the viscens at or near its center. The two loculi so formed may be almost equal in size, or one, generally the cardiac pouch, may be very much larger than the other. In one instance (Case 14) I have seen the stomach divided into three pouches, and in another (Case 15) a condition of hour-glass duodenum was associated with hour-glass stomach; so that four pouches, two larger in the stomach, two smaller in the duodenum, were seen. The isthmus connecting the two parts of the stomach is generally found at or near the middle of the viscus; but owing to stasis of the food, the cardiac complement becomes dilated, and is then much larger, thicker and more capacious than the pyloric. The pyloric pouch is, however, not seldom dilated also, and in such circumstances a pyloric or duodenal stenosis will also be found.

Pathogeny.—Hour-glass stomach is usually described as being "congenital" and "acquired." Of these forms, the congenital is said to be the more frequent.
